Coil Thickness and Packing of Cerebral Aneurysms: A Comparative Study of Two Types of Coils

Marjan J. Slob, Willem Jan van Rooij, and Menno Sluzewski

BACKGROUND AND PURPOSE: In coiling cerebral aneurysms, high packing prevents reopening over time. The purpose of this study was to compare packing of cerebral aneurysms treated with two types of coils with different wire thickness and different shapes.

METHODS: Packing, defined as the ratio between the volume of inserted coils and the volume of an aneurysm, was calculated for 144 cerebral aneurysms treated in 130 patients. Seventy-two aneurysms were treated with predominantly helical-shaped coils of 0.010-inch-diameter wire, and 72 aneurysms were treated with predominantly complex-shaped coils of 0.012-inch-diameter wire. Aneurysm volume was assessed from three-dimensional angiography. Aneurysm packing, inserted coil lengths, and numbers of coils were compared for both types of coils.

RESULTS: Mean packing was significantly higher (absolute value, 6.4%; relative value, 26.6%; \( P < .0001 \)) in aneurysms coiled with 0.012-inch-diameter coils than aneurysms coiled with 0.010-inch-diameter coils. Inserted coil length per cubic millimeter of aneurysmal volume was equal for both types of coils.

CONCLUSION: Use of complex-shaped coils with a wire diameter of 0.012 inch to coil cerebral aneurysms results in significantly better packing than is achieved with helical coils of 0.010-inch-diameter wire.

Over time, about 25% of cerebral aneurysms treated with coils show reopening of the lumen (1–2). Compaction of coil mesh (decrease of interspaces between the loops of the coils leading to a smaller coil mesh) is the most important contributing factor, and this phenomenon is believed to be caused by the waterhammer effect of pulsatile blood flow. Previous studies (3–5) have shown that compaction strongly relates to packing density, defined as the ratio of inserted coil volume to the volume of an aneurysm. Nonthrombosed aneurysms packed for 24% or more did not show compaction at 6-month follow-up angiography (3).

Higher aneurysm packing can be obtained by inserting higher volumes of coils. The volume of inserted coils is dependant on both coil thickness and inserted coil length. Theoretically, with equal inserted coil length, thicker coils should lead to higher packing than thinner coils. If using thicker coils implies that inserted coil length would be substantially lower, however, this positive effect of coil thickness on packing could be reduced. In the present study, we retrospectively compared the packing of aneurysms treated with helical coils of 0.010-inch diameter to packing of aneurysms treated with complex coils of 0.012-inch diameter.

Methods

Between March 17, 2003, and January 29, 2004, 166 patients with 180 cerebral aneurysms were treated with endovascular methods in our hospital. Twenty-one patients with 21 aneurysms had been coiled previously, five patients with five aneurysms larger than 15 mm were treated with 0.018-inch coils, and eight patients with eight aneurysms were treated with parent vessel occlusion. The remaining 146 aneurysms in 132 patients were treated with either 0.010-inch coils (Guglielmi detachable coil 10 regular, soft, and ultrasoft, three-dimensional and helical; Boston Scientific, Fremont, CA) or 0.012-inch coils (TruFill DCS complex and helical; Cordis, Miami, Fl). Coiling was performed by one of us (W.J.v.R. or M.S.), by using both types of coils in approximately equal numbers of patients. The choice of whether to use 0.010-inch or 0.012-inch coils was influenced by factors such as operator preference and availability of coils in stock, but the decision was independent of aneurysm or patient characteristics. In two of 132 patients (one in each group), the aneurysm ruptured during coiling and coils were placed outside the aneurysmal sac. These two patients were excluded from packing analysis but were included in assessment of procedure-related complications.

The present study group consists of 130 patients with 144 aneurysms. There were 88 women and 42 men with a mean age...

Results

Mean packing, aneurysm volume, inserted coil length per cubic millimeter of aneurysm, number of coils, and number of aneurysms with packing of more than 24% in both groups are listed in Table 1. There was no statistically significant difference in aneurysm volume in aneurysms treated with 0.010-inch coils versus 0.012-inch coils. Mean packing was significantly higher (absolute value, 6.4%; relative value, 26.6%) in aneurysms coiled with 0.012-inch coils than in aneurysms coiled with 0.010-inch coils. Proportion of aneurysms with packing of more than 24% was also significantly higher (absolute value, 36.1%; relative value, 89.6%) in aneurysms coiled with 0.012-inch coils. Inserted coil length per cubic millimeter of aneurysm was equal for both types of coils. The number of inserted coils was lower per filled aneurysm volume unit for aneurysms treated with 0.012-inch coils. Both types of coils show an inverse relation between aneurysm volume and packing (Fig 1).

Of the 132 patients treated with either type of coil, five patients (3.8%) suffered procedure-related complications leading to death or neurologic deficit during their hospital stay. Of these five patients, four were treated with 0.010-inch coils and one with 0.012-inch coils. This difference was not significant (P = 0.37).

Discussion

We found that complex-shaped coils with thickness of 0.012 inch packed significantly better than helical coils of 0.010 inch. This better packing can be explained by increased volume per coil length for thicker coils, because inserted coil length per cubic millimeter of aneurysm volume was found to be equal. The fact that equal lengths of 0.012-inch and 0.010-inch coils can be delivered per unit of aneurysm volume may be due to the complex shape of most inserted 0.012-inch coils, whereas most inserted...
0.010-inch coils were helical. An experimental study has already shown that complex-shaped coils allowed better aneurysm filling than did helical coils of the same diameter (6). The proportion of aneurysms packed for more than 24% was significantly higher for 0.012-inch coils than for 0.010-inch coils (76% vs. 40%). In a previous study, we found that nonthrombosed aneurysms packed for 24% or more did not show compaction at 6-month follow-up angiography. Therefore, it is plausible that more aneurysms treated with 0.012-inch coils will remain stable over time compared with aneurysms treated with 0.010-inch coils, but this has yet to be proved and is subject to ongoing evaluation. We also found that fewer 0.012-inch coils were necessary to obtain a significantly better packing compared with 0.010-inch coils. Perhaps the complex-shaped 0.012-inch coils achieve better concentric filling of the aneurysm, thereby creating less dead space than helical shaped coils. This allows the operator to keep on using larger diameter coils with complex—instead of helical—shapes to completely fill the aneurysm. Because larger coils are generally longer, fewer coils are needed.

A drawback of the present study is its retrospective and nonrandomized design. Aneurysm volumes were prospectively collected, however, and we are not aware of any selection bias in choosing type of coil in treatment of aneurysms. Possible errors in the measurement of aneurysm volume may have occurred as the result of differences in setting the threshold of the 3D data set and of manual segmentation of the aneurysm. In this study, aneurysm volume was measured by one of us (W.J.v.R. or M.S.), and threshold was set visually in conjunction with the histogram of the data set.

Recurrence of coiled cerebral aneurysms is probably related to a combination of factors—local hemodynamics, vessel geometry, the presence of intraluminal thrombus, and packing density. If it is shown that higher packing obtained with 0.012-inch coils in treatment of aneurysms leads to a reduction in reopening and retreatment rates compared with 0.010-inch coils, this will be an important step in improving the long-term stability of coiled cerebral aneurysms. We believe that future research should aim at finding optimal coil thickness and shape to obtain the highest possible packing and optimal mechanical occlusion of cerebral aneurysms. Coils coated with bioabsorbable material (7) might also contribute to better long-term results of coiled cerebral aneurysms, although in vivo evidence is lacking.

**Conclusion**

Coiling of cerebral aneurysms with complex-shaped 0.012-inch coils leads to significantly better packing than with helical-shaped 0.010-inch coils. Its impact on aneurysm recurrence remains uncertain but is the subject of ongoing evaluation.
