Abstract

We describe a new implementation of the BSD callout and timer facilities. Current BSD kernels take time proportional to the number of outstanding timers to set or cancel timers. Our implementation takes constant time to start, stop, and maintain timers; this leads to a highly scalable design that can support thousands of outstanding timers without much overhead. Unlike the existing implementation, our routines are guaranteed to lock out interrupts only for a small, bounded amount of time. We also extend the `setitimer()` interface to allow a process to have multiple outstanding timers, thereby reducing the need for users to maintain their own timer packages. The changes to the BSD kernel are small (548 lines of code added, 80 removed) and are available on the World Wide Web.

This work supported by a grant from the NSF.

Redesigning the BSD Callout and Timer Facilities

1. Introduction

To satisfy the needs of real-time applications and communication protocols, operating systems provide timers. In BSD[1] kernels, timers are provided by the callout facility, which allows a function and argument to be registered to be called at a future time. A clock interrupt routine periodically checks the outstanding callouts, and calls the functions due to be called.

There are four measures of performance of the callout facility:

1. Time to set a callout.
2. Time to cancel a callout.
3. Time to process a clock tick.
4. Time to process an expired callout.

Also of interest is the maximum amount of time that interrupts can be locked out during these operations. If interrupts are locked out for too long, time-critical I/O events may be missed by the system.

The existing implementation takes constant time (usually) to process a clock tick or an expired callout, but takes linear time (in the number of outstanding callouts) to set or cancel a callout. Interrupts are locked out for the duration of a set or cancel operation, which can take linear time in the number of outstanding callouts. Our new implementation achieves worst-case constant time for all operations except processing a clock tick, for which it achieves average-case constant time. It also never locks out interrupts for more than a constant amount of time.

Why Redesign? When we examined a typical UNIX workstation kernel, we found only 5–6 outstanding callouts (in use by RPC, NFS, and TCP). With such a small number of outstanding callouts, taking linear time to start or stop a callout is not very onerous, and the BSD implementation seems adequate. So why bother with a new implementation anyway?

Clearly, our new implementation is motivated by environments which have a large number of outstanding timers. Network protocol implementations provide the easiest example. Typically, for every packet sent by a reliable transport protocol such as TCP, a retransmission timer is started. If an acknowledgement arrives promptly, the timer is cancelled; when the timer expires, the packet is retransmitted. Several recent network implementations [CJRS89] have been tuned to send packets at a rate of 25,000–40,000 packets per second. The situation is exacerbated because most transport protocols use sliding window protocols (in which a large number of packets are allowed to be outstanding to allow pipelined throughput) and because servers often maintain several outstanding conversations with clients. Most other network protocols also use several timers for error recovery and rate control.

How then can the BSD TCP implementation get away with two callouts? This is possible because the TCP implementation maintains its own timers for all outstanding packets, and uses two kernel callouts as clocks to run its own timers.

[1] Throughout this paper, "BSD" refers to 4.4BSD-Lite and its derivatives, such as NetBSD.

TCP maintains its packet timers in the simplest fashion: Whenever its single kernel timer expires, it ticks away at all its outstanding packet timers. This method works reasonably well if the granularity of timers is low.[2] However, it is desirable to improve the resolution of the retransmission timer to allow speedier recovery.[3] With a large number of finer granularity timers, it is necessary to have more efficient timer algorithms. Rather than have every protocol duplicate these efficient algorithms [CJRS89, TNML93], it is better to have the kernel directly provide an efficient callout facility.

Besides networking applications, process control and other real-time applications will also benefit from large numbers of fine granularity timers. Also, the number of users on a system may grow large enough to lead to a large number of outstanding timers. This is the reason cited (for redesigning the timer facility) by the developers of the IBM VM/XA SP1 operating system[Dav89].

With a large number of outstanding callouts, it becomes important to bound the amount of time that interrupts can be locked out. Finally, regardless of the number of callouts, the current UNIX limit of one timer per process seems too restrictive. This forces user applications that need multiple timers either to fork additional processes or to maintain their own timers.

Therefore we believe that we can make a case for new callout and timer implementations that are scalable, robust, and flexible. Unlike many scalable designs, there is no performance penalty when the number of outstanding callouts is small. Also, the increase in the code size is small (158 lines for the new callout facility, and 310 lines for the extended interval timer facility). Thus, considering the general environments in which UNIX kernels are and will be deployed, the new implementation appears to be a wise and cheap piece of insurance.

Previous Work: Varghese and Lauck [VL87] described a number of new schemes to implement timers. The basis of our implementation is Scheme 6 in [VL87], which is based on a data structure called a hashed timing wheel. The work in [VL87] is mostly theoretical and does not consider some of the issues that occur in actual operating systems; for example, it assumes that all the per tick bookkeeping can be done at the interrupt level, which is clearly infeasible in a real system. A few fairly well known networking implementations (e.g., [CJRS89, TNML93]) have used the ideas in [VL87] in specialized timer packages for their networking routines (as opposed to a general operating system facility). Brown [Bro88] extends hashed timing wheels to what he calls calendar queues; the major difference is that calendar queue implementations also periodically resize the wheel in order to reduce the overhead[4] of stepping through empty buckets. For timer applications, the clock time must be incremented on every clock tick anyway; thus adding a few instructions to step through empty buckets is not significant. Davison [Dav89] describes a timer implementation for the IBM VM/XA SP1 operating system based on calendar queues. In our setting, the small improvement in per tick bookkeeping (from resizing the wheel periodically) does not appear to warrant the extra complexity of resizing.

Organization: The rest of the paper is organized as follows. Section 2 describes the existing NetBSD 1.0 kernel implementation of the callout facility. Section 3 reviews a timing wheel algorithm proposed in [VL87]. Section 4 illustrates how we implemented this algorithm in the NetBSD 1.0 kernel and the implementation issues that we encountered. We also describe in Section 5 an extension to the user-level interval timer facility to allow multiple outstanding timers; this was essential for the performance tests of the new callout facility, but we believe this feature is useful in its own right. Section 6 presents performance results. Section 7 describes future work in the areas of dynamic storage allocation and cleaning up the interval timer interface. Finally, Section 8 states our conclusions.

2. Existing Callout Implementation

In the existing BSD implementation, each callout is represented by a `callout` structure containing

[2] Currently TCP uses two virtual clocks: one with 200 ms ticks and one with 500 ms ticks.

[3] The larger the recovery time, the larger the amount of data that could have been sent, especially at high speeds. While packet loss due to corruption is rare today, packet loss due to congestion is still quite common.

[4] The improvement is not worst-case, but is demonstrated empirically for certain benchmarks.

a pointer to the function to be called (`c_func`), a pointer to the function's argument (`c_arg`), and a time (`c_time`) expressed in units of clock ticks. Outstanding callouts are kept in a linked list, sorted by their expiration times. The `c_time` member of each callout structure is differential, not absolute—the first callout in the list stores the number of ticks from now until expiration, and each subsequent callout in the list stores the number of ticks between its own expiration and the expiration of its predecessor.

Figure 1: The `calltodo` data structure.

This data structure (called `calltodo`, see Figure 1) dictates the performance. Because the times are differential, the clock interrupt routine `hardclock()` needs only to decrement the time of the first callout in the list and check whether it becomes zero, which takes constant time. If the first callout has expired, a software clock interrupt is generated. Its handler, `softclock()`, repeatedly checks the callout at the head of the list, and if it is expired (`c_time` member equal to zero), removes it and calls its function. Interrupts are locked out while the `calltodo` list is being manipulated, but not while the function is executing.

Callouts are set and canceled using `timeout()` and `untimeout()`, respectively. `timeout(func, arg, time)` registers `func(arg)` to be called at the specified time. `untimeout(func, arg)` cancels the callout with matching function and argument. Because the `calltodo` list must be searched linearly, both operations take time proportional to the number of outstanding callouts. Interrupts are locked out for the duration of the search.

There is one complication: Because the processing of expired callouts by `softclock()`, which can be interrupted by `hardclock()`, might take longer than one clock tick, callouts might become overdue. This is represented in the `calltodo` list by callouts at the start of the list with negative `c_time` members. A `c_time` member of $-t$ indicates that the callout is overdue by t ticks. `hardclock()` must decrement all non-positive `c_time` members at the beginning of the list, as well as the first positive `c_time` member in the list. Therefore, the processing of a clock tick does not necessarily take constant time (if there are a number of expired timers at the head of the list that `softclock()` has not yet processed).

3. Replacement Callout Algorithm

The algorithm used by the existing implementation is very similar to Scheme 2 of [VL87]. The new implementation is based on Scheme 6 of [VL87].

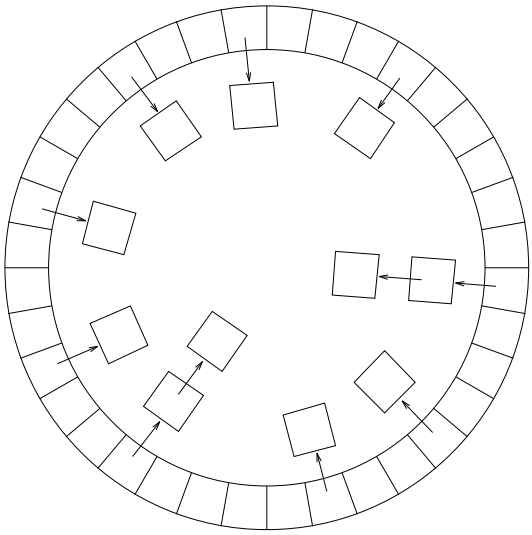

Figure 2: The `callwheel` data structure.

Instead of a single sorted list of callout structures, we use a circular array of unsorted lists. The array, called `callwheel` (see Figure 2), contains `callwheelsize` entries. All callouts scheduled to expire at time t appear in the list `callwheel[`t `% callwheelsize]`, and their `c_time` members are set to t `/ callwheelsize`. `callwheelsize` should be chosen to be comparable to the maximum possible number of outstanding callout structures.

On each clock tick, the appropriate list must be traversed completely, the `c_time` member of each callout in the list decremented, and the expired callouts handled and removed. In the worst case, all outstanding callouts could be in the same list, but since the number of lists is comparable to the maximum number of outstanding callouts, and the lists are processed in a round-robin fashion, the average list length is a small constant. Thus, it takes average-case constant time to process a clock tick. To handle an expired timer still requires nothing more than removing the callout from a list, which takes worst-case constant time, and then calling its function.

Setting a callout requires determining the appropriate list and inserting at the head, which takes worst-case constant time. For canceling a callout, the original Scheme 6 algorithm assumes that it will be given a handle to the callout (i.e. an identifier which locates the callout immediately), in which case it needs only to delete the callout from the list, taking worst-case constant time. But the existing `timeout()` interface does not use handles, so this becomes a problem in the implementation. Section 4 will describe how this problem has been overcome in two different ways. The original algorithm also assumes that each timer routine (especially the equivalent of `hardclock()`) runs to completion, and does not worry about the details of mutual exclusion and locking out interrupts. These problems are also addressed in Section 4.

4. Replacement Callout Implementation

`callwheelsize` is constrained to be a power of 2, equal to $2^{\texttt{callwheelbits}}$. This simplifies the division and remainder operations to bit shifting and masking. The lists in `callwheel` are doubly-linked (requiring an additional member in the `callout` structures), allowing the removal of a `callout` structure given only a pointer to it.

The old `hardclock()` had to manipulate the `calltodo` structure, but the new `hardclock()` has nothing to do but increment the global `ticks` variable[5] (which the old `hardclock()` did anyway), which represents the current time. `softclock()` has its own static variable, `softticks`. `softclock()` repeatedly checks whether `softticks` equals `ticks`, and if not, increments `softticks` and checks all the callouts in `callwheel[softticks & callwheelmask]`, expiring the ones with `c_time` members equal to zero, decrementing the `c_time` members of the others. As an optimization, after `hardclock()` increments `ticks`, it checks to see if `softticks` equals `ticks - 1` and `callwheel[ticks & callwheelmask]` is empty. If not, a software interrupt is generated to cause `softclock()` to run. Otherwise, `hardclock()` increments `softticks` itself rather than incur the overhead of a software interrupt, since that is all `softclock()` would have done.

Figures 3, 4, and 5 show the new code for `hardclock()` and `softclock()`.

If it were not for the lack of handles in the existing `timeout()`/`untimeout()` interface, the implementation of those functions would be straightforward, and there would be nothing to say about them here. There are two possible solutions to the problem. We could try to find a way, given a function pointer and argument pointer, to produce a pointer to the matching callout in constant time. A hash table is the obvious mechanism. The disadvantage is that a hash table cannot guarantee constant time in the worst case; it can only provide constant time in the expected case. The other solution would be to provide new interface functions called, say, `setcallout()` and `unsetcallout()`, which work very much like `timeout()` and `untimeout()`, except that `setcallout()` returns a handle, and `unsetcallout()` takes a handle as its only argument. The disadvantage here is that existing code elsewhere in the kernel already uses the existing interface. In the new implementation, both solutions are used. Both interfaces are available for adding and removing callouts to and from a single `callwheel`. A hash table is used only by the old interface.

At first, we used a closed-chaining hash table. If `untimeout(func, arg)` were called, and no outstanding callout matched the specified function and argument, the entire hash table would have to be searched. We did not expect `untimeout()` ever to be called this way, but it turns out that

[5] Actually, `hardclock()` also does other things entirely unrelated to the callout facility.

```
struct callout {
    struct  callout *c_next;          /* next callout in queue */
    struct  callout **c_back;         /* pointer back to the ptr */
                                      /* pointing at this struct */
    struct  callout *hash_next;       /* next and back pointers */
    struct  callout **hash_back;      /* for the callhash array */
    /* hash_back is NULL iff this callout is not in the hash table. */
    struct callout_handle {
        unsigned long lo, hi;
    } handle;                         /* handle for this callout */
    /* The lowest calloutbits of handle.hi are the   */
    /* index into the callout array of this callout. */
    void    *c_arg;                   /* function argument */
    void    (*c_func) __P((void *));  /* function to call */
    int     c_time;                   /* ticks to the event >> callwheelbits */
};

int ticks;                             /* Current time, in ticks. */
static int softticks;                  /* Like ticks, but for softclock(). */
static struct callout *nextsoftcheck;  /* Next callout to be checked. */
```

Figure 3: Declarations used by `hardclock()` and `softclock()`.

```
void hardclock(frame)
    register struct clockframe *frame;
{
    /* The real hardclock() also does other, non-callout-related things. */

    ticks++;

    if (callwheel[ticks & callwheelmask]) {  /* This condition changed. */
        if (CLKF_BASEPRI(frame)) {
            /* Save the overhead of a software interrupt;         */
            /* it will happen as soon as we return, so do it now. */
            (void)splsoftclock();
            softclock();
        } else
            setsoftclock();
    }
    else if (softticks + 1 == ticks) ++softticks;  /* This line is new. */
}
```

Figure 4: The new `hardclock()` function. From the old function, several lines dealing with `calltodo` have been removed, one line has been changed, and one line has been added.

```
void softclock()
{
    register struct callout *c;
    register int steps;          /* Number of steps taken since */
                                 /* we last allowed interrupts. */
    register int s;

    s = splhigh();
    steps = 0;
    while (softticks != ticks) {
        if (++steps >= MAX_SOFTCLOCK_STEPS) {
            nextsoftcheck = NULL;
            splx(s);  /* Give hardclock() a chance. */
            (void) splhigh();
            steps = 0;
        }
        c = callwheel[++softticks & callwheelmask];
        while (c) {
            if (c->c_time > 0) {
                --c->c_time;
                c = c->c_next;
                if (++steps >= MAX_SOFTCLOCK_STEPS) {
                    nextsoftcheck = c;
                    splx(s);  /* Give hardclock() a chance. */
                    (void) splhigh();
                    c = nextsoftcheck;
                    steps = 0;
                }
            }
            else {
                if (nextsoftcheck = *c->c_back = c->c_next)
                    nextsoftcheck->c_back = c->c_back;
                if (c->hash_back) callhash_remove(c);
                else if (++c->handle.lo == 0) c->handle.hi += calloutsize;
                splx(s);
                c->c_func(c->c_arg);
                (void) splhigh();
                steps = 0;
                c->c_next = callfree;
                callfree = c;
                c = nextsoftcheck;
            }
        }
    }
    nextsoftcheck = NULL;
    splx(s);
}
```

Figure 5: The new `softclock()` function. It is entirely different from the old one.

such calls are quite common. In the old implementation, the cost of canceling a non-existent callout was about the same as canceling an existent callout (both require a linear search of the `calltodo` structure). We wanted both sorts of calls to have equal costs in the new implementation as well, so we switched to an open-chaining hash table, in which only one bucket needs to be searched in any case. This required the addition of two more members to the `callout` structure, so that each callout, which might already belong to a doubly-linked list in `callwheel`, might also belong to a doubly-linked list in `callhash` (the hash table). `timeout()` always inserts the new callout into the hash table, and `untimeout()` always removes it, but `softclock()` must check to see whether an expiring callout is in the hash table before removing it. Fortunately, it need not compute the hash function to do this; it can merely check the links in the the `callout` structure.

The hash function was chosen to be fast to compute, but still provide a fairly even distribution among the buckets. `callhashsize` is constrained to be a power of 2, equal to $2^{\texttt{callhashbits}}$. Both the `func` and `arg` pointers are likely to be longword-aligned, so the lowest 2 bits of each are not used. The lower bits of function pointers are likely to be more random than the higher bits, so the next higher `callhashbits` bits of `func` are used. For data pointers, the low bits might be constant (in the case of pointers to large aligned structures, such as mbufs) or they might be the only bits that are significant (in the case of pointers into an array, for example). Therefore, we use not only the next higher `callhashbits` bits from `arg`, but also the next higher `callhashbits` bits above those. The three bit strings, each of length `callhashbits`, are aligned and XORed to produce the index into the hash table. The computation requires 3 shifts and 3 boolean operations.

For the new `setcallout()` interface, the design of the handle was not trivial. A simple pointer to a `callout` structure would not be safe, because those structures get recycled. Between the time `setcallout()` returns a pointer and the time `unsetcallout()` is passed that pointer, the callout could have expired and been reused, in which case the call to `unsetcallout()` will cancel someone else's callout. The solution was to give each `callout` structure an ID that gets incremented each time the callout is canceled by `unsetcallout()`. The ID is included in the handle, so that `unsetcallout()` can compare the IDs before canceling the callout. The size of the ID must be large enough that it will never wrap around. 32 bits was deemed insufficient. But the handle also needs to include a "pointer" to the `callout` structure, and a real pointer is overkill. Since all of the `callout` structures are allocated as a single array at boot time, we only need an index into this array, which takes `calloutbits` bits (this is much less than 32). So a `callout_handle` structure contains two unsigned longs, `lo` and `hi`. The lowest `calloutbits` bits of `hi` are the index into the `callout` array, and all remaining bits are used for the ID. Incrementing the ID amounts to incrementing `lo`, and if the result is zero, adding $\texttt{calloutsize} = 2^{\texttt{calloutbits}}$ to `hi`. Each `callout` structure contains a full `callout_handle` structure, with the lowest `calloutbits` bits of `hi` initialized at boot time, so that `unsetcallout()` may compare the entire handle, rather than just the ID portion.

The only remaining wrinkle in the implementation is motivated by the desire to limit the time that interrupts may be disabled. `timeout()` and `untimeout()`, which use the hash table, cannot guarantee a limit on the time that interrupts are disabled, but `setcallout()` and `unsetcallout()` can (and do). `hardclock()` always takes constant time.[6] The remaining concern is `softclock()`, which must lock out interrupts while it is manipulating the `callwheel` structure. While it is traversing a list (which could be long in the worst case), it cannot allow itself to be interrupted by `untimeout()` or `unsetcallout()`, because those functions might remove a `callout` structure right out from under `softclock()`. This problem was eliminated by a bit of unholy data-sharing between `softclock()` and `untimeout()` and `unsetcallout()`. As `softclock()` traverses a list, it uses a local pointer into the list. Whenever it wishes to enable interrupts briefly, it first copies its local pointer into the global variable `nextsoftcheck`, then enables interrupts, then disables interrupts, then copies `nextsoftcheck` back into its local pointer. Whenever `untimeout()` or `unsetcallout()` cancels a callout, it checks to see whether `nextsoftcheck`

[6] For its callout-related duties, that is.

points at the structure just removed, and if so, it sets `nextsoftcheck` to point to the next structure in the list. `softclock()` keeps track of the number of steps it has taken since it last enabled interrupts, and whenever the count reaches `MAX_SOFTCLOCK_STEPS`, it briefly enables them. Therefore, `softclock()` never disables interrupts for more than a constant amount of time. There are no guarantees on the timeliness of callout expirations, but there never were in the old implementation either.

5. Multiple Timers

Testing the performance of the new callout implementation would be easiest to do in a user-level process. A user process can cause callouts to be set, canceled, and expired via the interval timer facility, through the `getitimer()` and `setitimer()` system calls.

Unfortunately, the existing interval timer facility allows each process only one outstanding real-time timer, which means one outstanding callout. The first tests used multiple processes to achieve multiple outstanding callouts, but there were mysterious problems whenever more than 80 processes were spawned, no matter how high `MAXUSERS` was set.

While this was a pragmatic reason, we also believe that users will benefit from the ability to allow each process to have multiple outstanding real-time timers. Our extensions involved adding a new timer type tag, `ITIMER_MULTIREAL`, and overloading the semantics of the other arguments passed to `getitimer()` and `setitimer()`.

The details of the interface extensions are described in Figures 6 and 7. The extended interface allows the user process to create many real-time timers, which have 64-bit kernel-chosen handles associated with them, as well as 64-bit user-chosen labels. The user process can change the values and labels of existing timers, and destroy existing timers. Whenever a timer expires, the timer is put in a queue, and a `SIGALRM` is sent to the process. The process can pop an expired timer off of this queue and obtain both its handle and its label.

The implementation of the extended timer facility required much new code in the `getitimer()` and `setitimer()` system calls, of course. Also, two new pointer members were added to the `proc` structure to keep track of running and queued timers belonging to the processes.[7] Since each timer is represented by an `mrtimer` structure allocated from a shared pool, code needed to be added to `exit()` to free any timers still belonging to the dying process. Each `mrtimer` structure contains a pointer to the process that owns it, so one process cannot forge handles and trick the kernel into manipulating timers belonging to another process.

The kernel may be configured at compile-time to use either the `timeout()` interface or the `setcallout()` interface for the `ITIMER_MULTIREAL` facility.

6. Performance

Three kernels were tested on a Sun 4/360. All included the `ITIMER_MULTIREAL` facility. In one kernel, it used the `timeout()` interface to the old callout facility. In another kernel, it used the `timeout()` interface to the new callout facility. In the last kernel, it used the `setcallout()` interface to the new callout facility.

In each test, one process created a number of outstanding timers set for random times far in the future, causing a number of outstanding callouts. It then created one more timer, and repeatedly set it for a random time farther in the future than the others, causing repeated calls to `untimeout()` and `timeout()` (or `unsetcallout()` and `setcallout()`, depending on which kernel was being used). The results show that the time for the original callout facility increases linearly with the number of outstanding callouts, whereas the time for the replacement callout facility is constant with respect to the number of outstanding callouts, for both the old interface (using hashing) and the new interface (using handles). (See Figure 8 and Table 1.) The new interface performs very slightly better, and provides guaranteed constant time operations, but the old interface is needed for compatibility with the rest of the kernel.

[7] It would have been easier to use three pointers, but there were already 8 bytes of padding in the structure. By using only two pointers, it was possible to add the members without changing the size of the structure.

The existing interface, `setitimer(ITIMER_REAL, value, ovalue)`, sets the process's real-time interval timer to `value->it_value`, putting the former contents into `ovalue` if `ovalue` is not `NULL`. The timer decrements in real time, causing a `SIGALRM` when it reaches zero. If `value->it_interval` was not zero, the timer reloads with that value, otherwise it stops.

The new interface, `setitimer(ITIMER_MULTIREAL, value, ovalue)`, behaves similarly, but with the following differences:

- ovalue *must not* be `NULL`; it must point to a `struct itimerval`.
- If `value->it_value` is not zero, and `ovalue->it_value` is {`-1, -1`}, this is a create-new-timer operation. `ovalue->it_interval` must already be set to an arbitrary user-chosen "label" for the new timer. `ovalue->it_value` will be overwritten with a kernel-chosen "handle" for the timer. The timer will be initialized with `value`.
- If `value->it_value` is not zero, and `ovalue->it_value` is not {`-1, -1`}, this is a reset-existing-timer operation. `ovalue->it_value` is interpreted as a timer handle, and `ovalue->it_interval` must already be set to an arbitrary user-chosen label, which may differ from the existing timer's current label. The existing timer is removed from the expired timer queue (see `getitimer()`) if necessary, and its value and label are overwritten with `value` and `ovalue->it_interval`. As with `ITIMER_REAL`, `ovalue` is overwritten with the former value of the timer. If the handle in `ovalue->it_value` did not refer to an existing timer, `-1` is returned and `errno` is set to `EINVAL`.
- If `value->it_value` is zero, this is a cancel-timer operation. `value->it_interval` and `ovalue->it_interval` are ignored. `ovalue->it_value` is interpreted as a timer handle. If the handle is valid and the timer exists, it is destroyed, and its final value is stored in `ovalue`. Otherwise, `-1` is returned and `errno` is set to `EINVAL`. Note that timers in the expired queue (see `getitimer()`) are still considered to exist.

Figure 6: Extensions to `setitimer()`.

The existing interface, `getitimer(ITIMER_REAL, value)`, writes the current contents of the process's real-time interval timer into `value`.

The new interface, `getitimer(ITIMER_MULTIREAL, value)`, behaves similarly, but with the following differences:

- `value->it_value` must be set by the user before the call. `value->it_interval` is ignored.
- If `value->it_value` is {`-1, -1`}, this is a reap-expired-timer operation. As timers expire, they are enqueued. This call removes the timer at the head of the queue, writes its handle into `value->it_value`, and writes its label into `value->it_interval`. If the timer is not set up to reload, it is destroyed, otherwise it starts running again (its next expire time is based on it last expire time, not the time at which it was reaped). If the queue is empty, `-1` is returned and `errno` is set to `EAGAIN`. When a process exits, all of its running and queued timers are destroyed. It is impolite for a long-lived process to let timers expire and neither reap them nor cancel them, because that wastes system resources.
- In all other cases, `value->it_value` is interpreted as a timer handle. If the handle is valid and the timer exists, `value` is overwritten with the current timer value. Otherwise, it is left untouched, `-1` is returned, and `errno` is set to `EINVAL`.

Figure 7: Extensions to `getitimer()`.

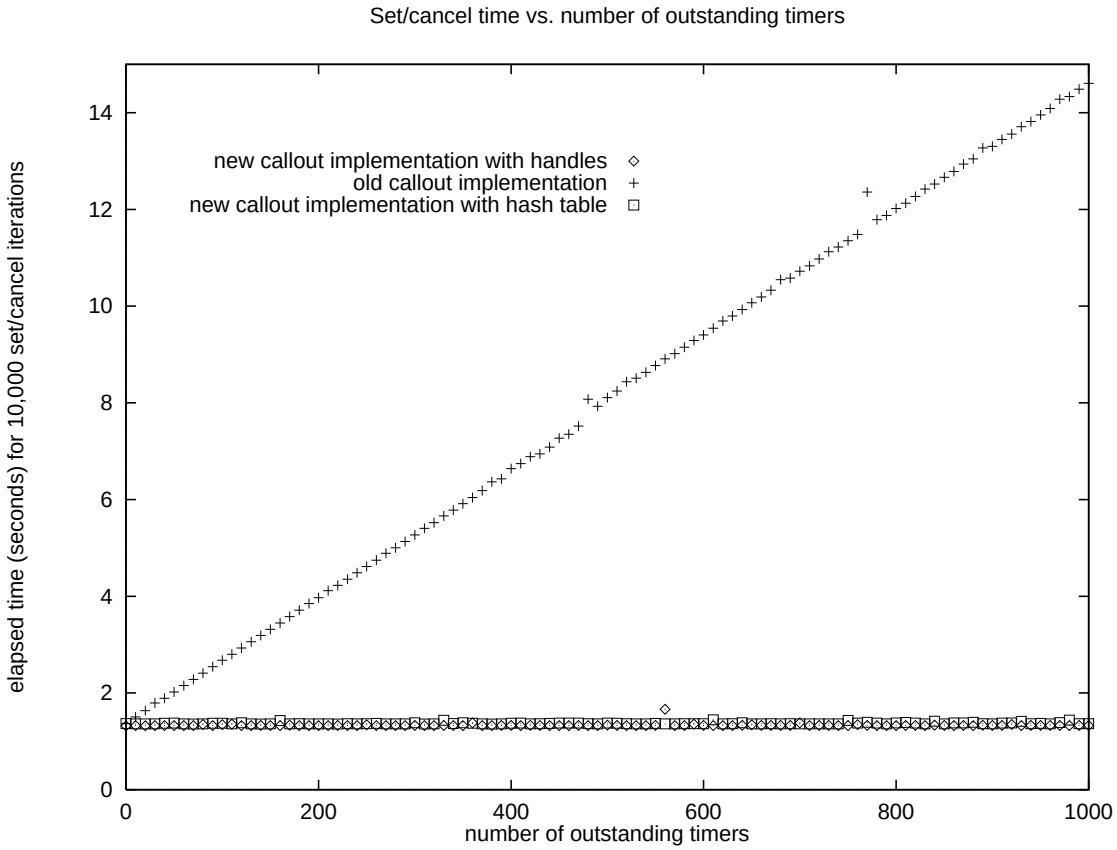

Figure 8: Real-time performance comparison of callout implementations.

Table 1: Selected data points from the graph of Figure 8.

	number of outstanding timers					
kernel	0	200	400	600	800	1000
old callout	1.367	3.969	6.638	9.404	12.017	14.608
new callout with hash table	1.366	1.360	1.377	1.363	1.379	1.364
new callout with handles	1.319	1.325	1.329	1.327	1.325	1.329

The exact number of outstanding callouts cannot be known exactly, because other parts of the kernel also use callouts. However, a search through the kernel code only revealed about 5 or 6 of them, being used by RPC, NFS, and TCP.

Table 2 shows the number of instructions required for the execution of each function. The longest paths were counted, except that instructions for changing the `hi` member of a `callout_handle` structure were never counted, because that happens in only one of every 2^{32} cases. The compiler used was gcc 2.4.5 for SPARC (which came with NetBSD) with the `-O2` option.

The performance of the new `hardclock()` and `softclock()` were not tested, but the instruction counts suggest that `hardclock()` performs about the same as before, while `softclock()` is about half as fast as before (given that usually $i = 1$, $j = 0$, and $k + m + n \leq 1$).

The memory usage of the new callout facility is within a constant factor of the original. Origi-

Table 2: Instruction counts for callout functions.

	instruction count	
function	*new version*	*original*
`hardclock`	37	$34 + 11v$
`softclock`	$27 + 20i + 15j +$ $12k + 54m + 37n$	$27 + 28e$
`timeout`	81	$46 + 11t$
`untimeout`	$80 + 11h$	$45 + 11t$
`setcallout`	60	
`unsetcallout`	55	

e callouts expire.
h callouts in a `callhash` bucket do not match.
i: `softclock` is incremented i times.
j: `MAX_SOFTCLOCK_STEPS` is reached j times.
k unexpired callouts are traversed.
m hashed callouts expire.
n non-hashed callouts expire.
t callouts are skipped in a search of `calltodo`.
v callouts are overdue at start of `calltodo`.

nally, n callout structures required $4n$ longwords. The new implementation needs $9n$ longwords for them, plus n to $2n$ for the `callwheel` array, plus $2n$ to $4n$ for the `callhash` array (unless the vast majority of the `callout` structures are intended for use with the `setcallout()` interface, in which case `callhash` is very small).

The `ITIMER_MULTIREAL` facility requires ten longwords per timer, plus two per process.

7. Future Work

Currently, the kernel panics if it runs out of callout structures. There was a comment in the old callout code saying that new callout structures should be allocated dynamically, and we would like to fulfill that wish. We will have to enlarge the `callout_handle` structure, because we will no longer be able to use an index into a single `callout` array—we will have to use an honest-to-goodness pointer. The ID will then have two unsigned longs all to itself.

There is a caveat: increasing the maximum possible number of outstanding callouts without increasing the size of `callwheel` or `callhash` could degrade performance, because the average list lengths could increase. Allowing `callwheel` and `callhash` to grow dynamically is conceivable, but probably not worth the effort.

We would also like to improve the appearance of the `ITIMER_MULTIREAL` facility. Although its design is functionally clean, the overloading of the `value` and `ovalue` parameters is distasteful. We would like to hide this overloading from the user, or at least provide alternate names for structure members which correspond to their usage.

Finally, we have just learned, to our dismay, that after we decided to use the two longwords of padding in the `proc` structure to support `ITIMER_MULTIREAL`, the NetBSD authors claimed one of those longwords for another purpose. This conflict will have to be resolved, probably by enlarging the structure.

8. Conclusion

We have described a new implementation of the NetBSD timer facility that appears to be more scalable, robust, and flexible than the current NetBSD implementation. It is scalable (see Figure 8) in that the overhead to start, stop, or maintain timers does not depend on the number of outstanding timers. It is robust in that we can precisely bound the amount of time interrupts are locked out in terms of a parameter, `MAX_SOFTCLOCK_STEPS`. It is flexible in that user processes are allowed to have multiple outstanding timers. The new implementation is fully compatible with existing software because existing interfaces are supported. However, applications that require slightly better performance (handles for deleting callouts) or flexibility (more than one outstanding timer) must use the new interfaces. The implementation does not incur any extra cost for these new features, and the code expansion is small (468 lines total[8]). The software is available for use or experiment at:
