Abstract. We generalize Cuckoo Hashing [23] to d -ary Cuckoo Hashing and show how this yields a simple hash table data structure that stores n elements in $(1 + \epsilon)n$ memory cells, for any constant $\epsilon > 0$. Assuming uniform hashing, accessing or deleting table entries takes at most $d = O(\ln \frac{1}{\epsilon})$ probes and the expected amortized insertion time is constant. This is the first dictionary that has worst case constant access time and expected constant update time, works with $(1 + \epsilon)n$ space, and supports satellite information. Experiments indicate that $d = 4$ choices suffice for $\epsilon \approx 0.03$. We also describe variants of the data structure that allow the use of hash functions that can be evaluated in constant time.

1 Introduction

The efficiency of many programs crucially depends on hash table data structures, because they support constant expected access time. We also know hash table data structures that support *worst case* constant access time for quite some time [12, 9]. Such worst case guarantees are relevant for real time systems and parallel algorithms where delays of a single processor could make all the others wait. A particularly fast and simple hash table with worst case constant access time is *Cuckoo Hashing* [23]: Each element is mapped to two tables t_1 and t_2 of size $(1 + \epsilon)n$ using two hash functions h_1 and h_2 , for any $\epsilon > 0$. A factor above two in space expansion is sufficient to ensure with high probability that each element e can be stored either in $t_1[h_1(e)]$ or $t_2[h_2(e)]$. The main trick is that insertion moves elements to different table entries to make room for the new element.

To our best knowledge, all previously known hash tables with worst case constant access time and sublinear insertion time share the drawback of a factor at least two in memory blowup. In contrast, hash tables with only expected constant access time that are based on open addressing can work with memory consumption $(1 + \epsilon)n$. In the following, ϵ stands for an arbitrary positive constant.

The main contribution of this paper is a hash table data structure with worst case constant access time and memory consumption only $(1 + \epsilon)n$. The access time is $O(\ln \frac{1}{\epsilon})$ which

^{*} A preliminary version of this work appeared in the Proceedings of the 20th Annual Symposium on Theoretical Aspects of Computer Science (STACS 2003), Lecture Notes in Computer Science 2607. is in some sense optimal, and the expected insertion time is also constant. The proposed algorithm is a rather straightforward generalization of Cuckoo Hashing to *d*-ary *Cuckoo Hashing*: Each element is stored at the position dictated by one out of *d* hash functions. In our analysis, insertion is performed by Breadth First Search (BFS) in the space of possible ways to make room for a new element. In order to ensure that the amount of memory used for bookkeeping in the BFS is negligible, we limit the number of nodes that can be searched to $o(n)$, and perform a rehash if this BFS does not find a way of accommodating the elements. For practical implementation, a random walk can be used. Unfortunately, the analysis that works for the original (binary) Cuckoo Hashing and $\log n$ -wise independent hash functions [23] breaks down for $d \geq 3$. Therefore we develop new approaches and give an analysis of the simple algorithm outlined above for the case that hash functions are truly random. As observed by Dietzfelbinger [6], similar results can be obtained for the family of hash functions described in [21] and [10], which can be evaluated in constant time.

We also provide experimental evidence which indicates that *d*-ary Cuckoo Hashing is even better in practice. For example, at $d = 4$, we can achieve 97% space utilization and at 90% space utilization, insertion requires only about 20 memory probes on the average, i.e., only about a factor two more than for $d = \infty$.

We also present *Filter Hashing*, an alternative to *d*-ary Cuckoo Hashing that uses polynomial hash functions of degree $O(\sqrt{d})$. It has the same performance as *d*-ary Cuckoo Hashing except that it uses $d = O(\ln^2 \frac{1}{\epsilon})$ probes for an access in the worst case.

A novel feature of both *d*-ary Cuckoo Hashing (in the random-walk variant implemented for the experiments) and Filter Hashing is that we use hash tables having size only a fraction of the number of elements hashed to them. This means that high space utilization is ensured, even though there is only one possible location for an element in each table. Traditional hashing schemes use large hash tables where good space utilization is achieved by having many possible locations for each element.

1.1 Related Work

Space efficient dictionaries. A *dictionary* is a data structure that stores a set of elements, and associates some piece of information with each element. Given an element, a dictionary can look up whether it is in the set, and if so, return its associated information. Usually elements come from some universe of bounded size. If the universe has size m , the information theoretical lower bound on the number of bits needed to represent a set of n elements (without associated information) is $B = n \log(em/n) - \Theta(n^2/m) - O(\log n)$. This is roughly $n \log n$ bits less than, say, a sorted list of elements. If $\log m$ is large compared to $\log n$, using n words of $\log m$ bits is close to optimal.

A number of papers have given data structures for storing sets in near-optimal space, while supporting efficient lookups of elements, and other operations. Cleary [4] showed how to implement a variant of linear probing in space $(1 + \epsilon)B + O(n)$ bits, under the assumption that a truly random permutation on the key space is available. The expected average time for lookups and insertions is $O(1/\epsilon^2)$, as in ordinary linear probing. A space usage of $B +$

$o(n) + O(\log \log m)$ bits was obtained in [22] for the *static* case. Both these data structures support associated information using essentially optimal additional space.

Other works have focused on dictionaries *without* associated information. Brodnik and Munro [3] achieve space $O(B)$ in a dictionary that has worst case constant lookup time and amortized expected constant time for insertions and deletions. The space usage was recently improved to $B + o(B)$ bits by Raman and Rao [24]. Since these data structures are not based on hash tables, it is not clear that they extend to support associated information. In fact, Raman and Rao mention this extension as a goal of future research.

Our generalization of Cuckoo Hashing uses a hash table with $(1 + \epsilon)n$ entries of $\log m$ bits. As we use a hash table, it is trivial to store associated information along with elements. The time analysis depends on the hash functions used being truly random. For many practical hash functions, the space usage can be decreased to $(1 + \epsilon)B + O(n)$ bits using *quotienting* (as in [4, 22]). Thus, our scheme can be seen as an improvement of the result of Cleary to worst case lookup bounds (even having a better dependence on ϵ than his average case bounds). However, there remains a gap between our experimental results for insertion time and our theoretical upper bound, which does not beat Cleary's.

Open addressing schemes. Cuckoo Hashing falls into the class of open addressing schemes, as it places keys in a hash table according to a sequence of hash functions. The worst case $O(\ln(1/\epsilon))$ bound on lookup time matches the *average* case bound of classical open addressing schemes like double hashing. Yao [29] showed that this bound is the best possible among all open addressing schemes that do not move elements around in the table. A number of hashing schemes move elements around in order to improve or remove the dependence on ϵ in the average lookup time [1, 13, 16, 17, 25].

In the classical open addressing schemes some elements can have a retrieval cost of $\Omega(\frac{\log n}{\log \log n})$. Bounding the worst case retrieval cost in open addressing schemes was investigated by Rivest [25], who gave a polynomial time algorithm for arranging keys so as to minimize the worst case lookup time. However, no bound was shown on the expected worst case lookup time achieved. Rivest also considered the dynamic case, but the proposed insertion algorithm was only shown to be expected constant time for low load factors (in particular, nothing was shown for $\epsilon \leq 1$).

Matchings in random graphs. Our analysis uses ideas from two seemingly unrelated areas that are connected to Cuckoo Hashing by the fact that all three problems can be understood as finding matchings in some kind of random bipartite graphs.

The proof that space consumption is low is similar in structure to the result in [28, 27] that two hash functions suffice to map n elements (disk blocks) to D places (disks) such that no disk gets more than $\lceil n/D \rceil + 1$ blocks. The proof details are quite different however. In particular, we derive an analytic expression for the relation between ϵ and d . Similar calculations may help to develop an analytical relation that explains for which values of n and D the “+1” in $\lceil n/D \rceil + 1$ can be dropped. In [27] this relation was only tabulated for small values of n/D .

The analysis of insertion time uses expansion properties of random bipartite graphs. Motwani [20] uses expansion properties to show that the algorithm by Hopcroft and Karp [14] finds perfect matchings in random bipartite graphs with $m > n \ln n$ edges in expected time $O(m \log n / \log \log n)$. He shows an $O(m \log n / \log d)$ bound for the d -out model of random bipartite graphs, where all nodes are constrained to have degree at least $d \geq 4$.

Our analysis of insertion can be understood as an analysis of a simple incremental algorithm for finding perfect matchings in a random bipartite graph where n nodes on the left side are constrained to have constant degree d whereas there are $(1 + \epsilon)n$ nodes on the right side without a constraint on the degree. We feel that this is a more natural model for sparse graphs than the d -out model because there seem to be many applications where there is an asymmetry between the two node sets and it is unrealistic to assume a lower bound on the degree of a right node (e.g., [28, 26, 27]).

Under these conditions we get *linear* run time even for very sparse graphs using a very simple algorithm that has the additional advantage to allow incremental addition of nodes. The main new ingredient in our analysis is that besides expansion properties, we also prove *shrinking properties* of nodes not reached by a BFS. An aspect that makes our proof more difficult than the case in [20] is that our graphs have weaker expansion properties because they are less dense (or less regular for the d -out model).

1.2 Overview

In Section 2, we introduce Cuckoo Hashing as a matching problem in a class of random bipartite graphs. Section 3 constitutes the main part of the paper. In Section 3.1, we prove that for $d \geq 2(1 + \epsilon) \ln(\frac{e}{\epsilon})$ and truly random hash functions, d -ary Cuckoo Hashing results in bipartite graphs which contain a matching covering all left vertices/elements with high probability (henceforth “whp.”¹). In Section 3.2, we show that for somewhat larger values of d , an incremental algorithm which augments along a shortest augmenting path takes $(1/\epsilon)^{O(\ln d)}$ expected time per element and visits at most $o(n)$ vertices before it finds an augmenting path whp. Section 4 complements the theoretical analysis by experiments which justify the practical efficiency of d -ary Cuckoo Hashing. Filter Hashing is presented and analyzed in Section 5. We show that for $d = \Theta(\ln^2 \frac{1}{\epsilon})$ and polynomial hash functions of degree $O(\ln \frac{1}{\epsilon})$, Filter Hashing stores almost all elements (e.g., at least $(1 - \frac{\epsilon}{4})n$ of them) in n memory cells whp. Some directions for further research and a modification of d -ary Cuckoo Hashing for hash functions that can be evaluated in constant time are discussed in Section 6.

2 Preliminaries

A natural way to define and analyze d -ary Cuckoo Hashing and Filter Hashing is through matchings in random bipartite graphs. The elements can be thought of as the left vertices and the memory cells as the right vertices of a bipartite graph $B(L, R, E)$. The edges of B are determined by the hash functions. An edge connecting a left vertex to a right vertex

¹ In this paper “whp.” will mean “with probability at least $1 - O(1/n)$ ”.

indicates that the corresponding element can be stored in the corresponding memory cell. Any one-to-one mapping of elements/left vertices to memory cells/right vertices forms a matching in B . Since every element is stored in some cell, this matching is L -perfect, i.e., it covers all the left vertices of B .

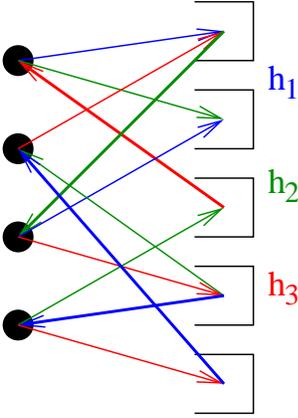

Fig. 1. Ternary Cuckoo Hashing ($d = 3$).

Having fixed an L -perfect matching M , we can think of B as a directed graph, where the edges in $E \setminus M$ are directed from left to right and the edges in M are directed from right to left (Fig. 1). Therefore, each right vertex has outdegree at most one. The set of *free vertices* $F \subseteq R$ simply consists of the right vertices with no outgoing edges (i.e., zero outdegree). Then, any directed path from an unmatched left vertex v to F is an augmenting path for M , because if we reverse the edge directions along such a path, we obtain a new matching which also covers v .

We always use X to denote a set of left vertices and Y to denote a set of right vertices. For a set of left vertices X , let $M(X)$ denote the set of X 's mates according to the current matching M . For a set of vertices $S \subseteq L \cup R$, let $\Gamma(S)$ denote the neighborhood of S , i.e., $\Gamma(S) = \{v : \{u, v\} \in E, u \in S\}$. We should emphasize that whenever we use $\Gamma(S)$ or refer to the neighborhood of a vertex set, we consider the edges as undirected.

In the analysis of d -ary Cuckoo Hashing, we repeatedly use the following upper bound on binomial coefficients.

Proposition 1. *Given an integer n , for any integer k , $1 \leq k \leq n$,*

$$\binom{n}{k} \leq \left(\frac{n}{n-k}\right)^{n-k} \binom{n}{k}.$$

Proof. For completeness, we give a simple proof communicated to us by M. Dietzfelbinger [6]. Let $\mu = \frac{k}{n} \in (0, 1]$. We observe that

$$\begin{aligned} \binom{n}{k} \mu^k (1-\mu)^{n-k} &\leq \sum_{j=0}^n \binom{n}{j} \mu^j (1-\mu)^{n-j} \\ &= (\mu + (1-\mu))^n = 1, \end{aligned}$$

which implies the proposition. □

3 d -ary Cuckoo Hashing

In d -ary Cuckoo Hashing, we consider n elements stored in $(1 + \epsilon)n$ memory cells. Each element is stored in one out of d cells chosen uniformly at random and independently with replacement. Consequently, the resulting bipartite graph $B(L, R, E)$ has $|L| = n$ and $|R| = (1 + \epsilon)n$. Each left vertex has exactly d neighbors selected uniformly at random and independently (with replacement) from R .

3.1 Existence of an L -Perfect Matching

We start by proving that for sufficiently large values of d , such bipartite graphs contain an L -perfect matching whp.

Lemma 1. *Given a constant $\epsilon \in (0, 1)$, for any integer $d \geq 2(1+\epsilon) \ln(\frac{\epsilon}{c})$, the bipartite graph $B(L, R, E)$ contains an L -perfect matching with probability at least $1 - O(n^{4-2d})$.*

Proof. We establish a bound of $O(n^{4-2d})$ on the probability that there exists a set of left vertices X having less than $|X|$ neighbors. Then, the lemma follows from Hall's Theorem (e.g., [5], Chapter 2), which states that a bipartite graph contains an L -perfect matching if and only if any $X \subseteq L$ has at least $|X|$ neighbors.

For a fixed integer k , $2 \leq k \leq n$, let $P(k)$ be the probability that there exists a set of k left vertices with at most k neighbors. The probability that the bipartite graph B does not contain an L -perfect matching is bounded by the sum of the probabilities $P(k)$ over all integers $2 \leq k \leq n$.

For an integer k , we fix a set of left vertices X and a set of right vertices Y both of size k . The probability that Y includes all neighbors of X is $(\frac{k}{(1+\epsilon)n})^{dk}$. Multiplying by the number of different sets X and Y , we obtain that

$$P(k) \leq \binom{n}{k} \binom{(1+\epsilon)n}{k} \left(\frac{k}{(1+\epsilon)n} \right)^{dk}.$$

For $k = 2$, the probability that there exists a pair of left vertices with a single neighbor in R is $O(n^{3-2d})$. Let c be a sufficiently large constant. For $k \leq \frac{n}{c}$, using $\binom{n}{k} \leq (\frac{en}{k})^k$, we get the following upper bound on $P(k)$.

$$P(k) \leq \frac{e^{2k} k^{(d-2)k}}{n^{(d-2)k}}$$

If $c > e^{\frac{d}{d-2}}$, the right-hand side of the inequality above is a non-increasing function of k and cannot exceed $O(n^{3-2d})$, for any $d \geq 3$. Therefore, for any $3 \leq k \leq \frac{n}{c}$, $P(k) = O(n^{3-2d})$.

For $\frac{n}{c} < k \leq n$, let $\mu = \frac{k}{n} \in (0, 1]$. Using Proposition 1, we obtain the following bound on the probability $P(\mu n)$.

$$P(\mu n) \leq \left[\left(\frac{1}{1-\mu} \right)^{1-\mu} \left(\frac{1}{\mu} \right)^{\mu} \left(\frac{1+\epsilon}{1+\epsilon-\mu} \right)^{1+\epsilon-\mu} \left(\frac{1+\epsilon}{\mu} \right)^{\mu} \left(\frac{\mu}{1+\epsilon} \right)^{d\mu} \right]^n$$

The value of d should make the quantity in square brackets strictly smaller than 1. Solving the resulting inequality, we obtain the following lower bound on d :

$$d > 1 + \frac{\mu \ln(\frac{1}{\mu}) + (1-\mu) \ln(\frac{1}{1-\mu}) + (1+\epsilon-\mu) \ln(\frac{1+\epsilon}{1+\epsilon-\mu})}{\mu \ln(\frac{1+\epsilon}{\mu})} \quad (1)$$

To simplify Inequality (1), we observe that:

1. For all $\epsilon \in (0, 1)$ and $\mu \in (0, 1]$, $\mu \ln(\frac{1}{\mu}) < \mu \ln(\frac{1+\epsilon}{\mu})$.
2. For any fixed value of $\epsilon \in (0, 1)$, $\frac{(1+\epsilon-\mu) \ln(\frac{1+\epsilon}{1+\epsilon-\mu})}{\mu \ln(\frac{1+\epsilon}{\mu})}$ is a non-decreasing function of μ in the interval $(0, 1]$. Hence, it is maximized for $\mu = 1$ achieving the value of $\frac{\epsilon \ln(\frac{1+\epsilon}{\epsilon})}{\ln(1+\epsilon)}$.

We also need the following proposition. For completeness, we provide a simple proof of Proposition 2 in the Appendix.

Proposition 2. *For all $\epsilon \in (0, 1)$ and $\mu \in (0, 1]$, $\frac{(1-\mu) \ln(\frac{1}{1-\mu})}{\mu \ln(\frac{1+\epsilon}{\mu})} \leq \frac{\epsilon \ln(\frac{1+\epsilon}{\epsilon})}{\ln(1+\epsilon)}$.*

Consequently, for any integer $d \geq 2 + \frac{2\epsilon \ln(\frac{1+\epsilon}{\epsilon})}{\ln(1+\epsilon)}$, the bipartite graph B contains an L -perfect matching with probability at least $1 - O(n^{4-2d})$. A brief calculation using $\ln(1+\epsilon) > \epsilon - \epsilon^2/2$ shows that the above inequality is satisfied whenever $d \geq 2(1+\epsilon) \ln(\frac{\epsilon}{\epsilon})$. \square

By directly applying Inequality (1) for specific values of ϵ , we obtain that if $\epsilon \geq 0.57$ and $d = 3$, if $\epsilon \geq 0.19$ and $d = 4$, and if $\epsilon \geq 0.078$ and $d = 5$, the bipartite graph B contains an L -perfect matching whp. The experiments in Section 4 indicate that even smaller values of ϵ are possible.

We also show that the bound of Lemma 1 on d is essentially best possible.

Lemma 2. *If $d < (1+\epsilon) \ln(1/\epsilon)$ then $B(L, R, E)$ does not contain a perfect matching whp.*

Proof. We can think of the right vertices as bins and the edges as balls. Each ball is placed in a bin selected uniformly at random and independently. We have exactly $(1+\epsilon)n$ bins and dn balls. The expected number of empty bins/isolated right vertices approaches $(1+\epsilon)n e^{-\frac{d}{1+\epsilon}}$ as n goes to infinity (e.g., [19, Chapter 3]). Let β be a positive constant. For n being larger than a suitable constant, if d is smaller than $(1+\epsilon) \ln(\frac{1+\epsilon}{(1+\beta)\epsilon})$, the expected number of isolated right vertices is greater than $(1 + \frac{\beta}{2})\epsilon n$. Furthermore, since the events “the right vertex v is isolated” are negatively associated (e.g., [11]), we can apply the Chernoff bound (e.g., [19, Chapter 4]) and show that if $d < (1+\epsilon) \ln(\frac{1+\epsilon}{(1+\beta)\epsilon})$, the number of isolated right vertices is greater than ϵn whp. Clearly, a bipartite graph B with more than ϵn isolated right vertices cannot contain an L -perfect matching. The lemma is obtained by setting $\beta = \epsilon$. \square

3.2 The Insertion Algorithm

To define and analyze the insertion algorithm for d -ary Cuckoo Hashing, we assume that the left vertices of the bipartite graph B arrive (along with their d random choices/edges) one-by-one in an arbitrary order and the algorithm incrementally maintains an L -perfect matching in B .

Let M be an L -perfect matching fixed before a left vertex v arrives. We recall that the edges in M are considered to be directed from right to left, while the edges not in M are directed from left to right. All the edges of v are initially directed from left to right, because v is not matched by M . We also recall that any directed path from v to the set of free vertices F is an augmenting path for M .

The insertion algorithm we analyze always augments the current matching along a shortest directed path from v to F . Such a path can be found by the equivalent of a Breadth First Search (BFS) in the directed version of B , which is implicitly represented by the d hash functions and the storage table. We ensure space efficiency by restricting the number of right vertices the BFS can visit to $o(n)$.

To avoid any dependencies among the random choices of a newly arrived left vertex and the current matching, we restrict our attention to the case where a left vertex that has been deleted from the hash table cannot be re-inserted². The remaining section is devoted to the proof of the following theorem.

Theorem 1. *For any positive $\epsilon < 1/5$ and integer $d \geq 5 + 3 \ln(1/\epsilon)$, the incremental algorithm that augments along a shortest augmenting path takes $(1/\epsilon)^{O(\ln d)}$ expected time per left vertex/element to maintain an L -perfect matching in B . Moreover, the algorithm visits at most $o(n)$ right vertices before it finds an augmenting path whp.*

Remark. Using the same techniques, we can prove that Theorem 1 holds for any $\epsilon \in (0, 1)$. For ease of exposition, we restrict our attention to the most interesting case of small ϵ .

Augmentation Distance. In the proof of Theorem 1, we measure the distance from a vertex v to the set of free vertices F by only accounting for the number of left to right edges (*free edges* for short), or, equivalently, the number of left vertices appearing in a shortest path (respecting the edge directions) from v to F . We refer to this distance as the *augmentation distance* of v . We should emphasize that the augmentation distance of a vertex depends on the current matching M .

The augmentation distance of a vertex v essentially measures the depth at which a BFS starting from v reaches F for the first time. Therefore, if a new left vertex has a neighbor at augmentation distance λ , a shortest augmenting path can be found in $O(d^{\lambda+1})$ time and space. To establish Theorem 1, we bound the number of right vertices at large augmentation distance.

Outline. The proof of Theorem 1 is divided in three parts. We first prove that the number of right vertices at augmentation distance at most λ grows exponentially with λ , whp., until almost half of the right vertices have been reached. We call this the *expansion property*. We next prove that for the remaining right vertices, the number of right vertices at augmentation distance greater than λ decreases exponentially with λ , whp. We call this the *shrinking property*. The proofs of both the expansion property and the shrinking property are based on the fact that for an appropriate choice of d , d -ary Cuckoo Hashing results in bipartite graphs which are good expanders, whp. Finally, we put the expansion property and the shrinking property together to show that the number of right vertices encountered by a BFS before an augmenting path is found is at most $o(n)$ whp. and the expected insertion time per element is constant.

² This restriction on deletions is easily overcome by just *marking* deleted elements, and only removing them when periodically rebuilding the hash table with new hash functions.

Notation. For an integer λ , let Y_λ denote the set of right vertices at augmentation distance at most λ , and let X_λ denote the set of left vertices at augmentation distance at most λ . The sets X_λ and Y_λ can be computed inductively starting from the set of free vertices F . For $\lambda = 0$, $Y_0 = F$ and $X_0 = \emptyset$. For any integer $\lambda \geq 1$, we have $X_{\lambda+1} = \Gamma(Y_\lambda)$ and $Y_{\lambda+1} = M(X_{\lambda+1}) \cup F$.

The Expansion Property. We first prove that if d is chosen appropriately large, any set of right vertices Y of size in the interval $[\epsilon n, 3n/8]$ expands by a factor no less than $4/3$ whp. (Lemma 3). This implies that the number of right vertices at augmentation distance at most λ is at least $(1+(4/3)^\lambda)\epsilon n$, as long as λ is so small that this number does not exceed $(1/2+\epsilon)n$ (Lemma 5).

Lemma 3. *Given a constant $\epsilon \in (0, 1/5)$, let $d \geq 5 + 3 \ln(1/\epsilon)$ be an integer. Then, any set of right vertices Y , $\epsilon n \leq |Y| \leq 3n/8$ has at least $4|Y|/3$ neighbors with probability at least $1 - 2^{-\Omega(n)}$.*

Proof. We first establish the following lemma whose proof is similar to the proof of Lemma 1.

Lemma 4. *Given a constant $\epsilon \in (0, 1/5)$, let δ be any positive constant not exceeding $\frac{4(1-4\epsilon)}{1+4\epsilon}$, and let d be any integer such that*

$$d \geq 3 + 2\epsilon + 2\delta(1 + \epsilon) + \frac{(2 + \delta)\epsilon \ln\left(\frac{1+\epsilon}{\epsilon}\right)}{\ln(1 + \epsilon)} .$$

Then, any set of left vertices X , $\frac{n}{2} \leq |X| \leq (1 - (1 + \delta)\epsilon)n$, has at least $(1 + \epsilon)n - \frac{n-|X|}{1+\delta}$ neighbors with probability at least $1 - 2^{-\Omega(n)}$.

Proof. Let μ be any number in the interval $[\epsilon, \frac{1}{2(1+\delta)}]$ such that $(1 - (1 + \delta)\mu)n$ is an integer. For simplicity of presentation and without loss of generality, we assume that $(1 + \epsilon - \mu)n$ is also an integer. Let $P(\mu)$ be the probability that the bipartite graph B contains a set of left vertices X of size $(1 - (1 + \delta)\mu)n$ with at most $(1 + \epsilon - \mu)n$ neighbors in R . We bound the probability that the graph B does not satisfy the conclusion of the lemma by the sum of the probabilities $P(\mu)$ over all the different values of μ for which $(1 - (1 + \delta)\mu)n$ is an integer.

For a fixed value of μ , we fix a set of left vertices X of size $(1 - (1 + \delta)\mu)n$ and a set of right vertices Y of size $(1 + \epsilon - \mu)n$. The probability that all neighbors of X are included in Y is $\left(\frac{1+\epsilon-\mu}{1+\epsilon}\right)^{d(1-(1+\delta)\mu)n}$. Multiplying by the number of different sets X and Y , we obtain the following upper bound on $P(\mu)$.

$$P(\mu) \leq \binom{n}{(1 + \delta)\mu n} \binom{(1 + \epsilon)n}{\mu n} \left(\frac{1 + \epsilon - \mu}{1 + \epsilon}\right)^{d(1-\mu(1+\delta))n}$$

Using Proposition 1 and working as in the proof of Lemma 1, we obtain the following lower bound on d .

$$d > \frac{(1 - \mu(1 + \delta)) \ln\left(\frac{1}{1-(1+\delta)\mu}\right) + (1 + \delta)\mu \ln\left(\frac{1}{(1+\delta)\mu}\right) + (1 + \epsilon - \mu) \ln\left(\frac{1+\epsilon}{1+\epsilon-\mu}\right) + \mu \ln\left(\frac{1+\epsilon}{\mu}\right)}{(1 - \mu(1 + \delta)) \ln\left(\frac{1+\epsilon}{1+\epsilon-\mu}\right)}$$

For all $\epsilon \in (0, 1/5)$ and $\delta \in (0, \frac{4(1-4\epsilon)}{1+4\epsilon}]$, the right-hand side of the above inequality is maximized for $\mu = \epsilon$ yielding the following lower bound on d .

$$d > \frac{(1 - \epsilon(1 + \delta)) \ln(\frac{1}{1-(1+\delta)\epsilon}) + (1 + \delta)\epsilon \ln(\frac{1}{(1+\delta)\epsilon}) + \ln(1 + \epsilon) + \epsilon \ln(\frac{1+\epsilon}{\epsilon})}{(1 - \epsilon(1 + \delta)) \ln(1 + \epsilon)} \quad (2)$$

The right-hand side of Inequality (2) can be simplified by observing that $\ln(\frac{1}{(1+\delta)\epsilon}) < \ln(\frac{1+\epsilon}{\epsilon})$. In addition, for all $\delta \in (0, \frac{4(1-4\epsilon)}{1+4\epsilon}]$, $\frac{1}{1-(1+\delta)\epsilon} \leq 1 + 2\epsilon(1 + \delta)$, and $\frac{\ln(\frac{1}{1-(1+\delta)\epsilon})}{\ln(1+\epsilon)} \leq 2(1 + \delta)$.

Since $\mu \geq \epsilon$ and there are at most n different values of μ to consider, the probability that the graph B does not have the claimed property is at least $1 - O(n\beta^n)$, for some constant $\beta < 1$ depending on the choice of d . \square

Then, we show that any bipartite graph B satisfying the conclusion of Lemma 4 also satisfies the conclusion of Lemma 3. To reach a contradiction, we assume that for some $\mu \in [\epsilon, \frac{1}{2(1+\delta)}]$, there is a set $Y \subseteq R$ of size μn with less than $(1 + \delta)\mu n$ neighbors in L . Let X be the set of left vertices not included in the neighborhood of Y . Then, X consists of more than $(1 - (1 + \delta)\mu)n$ vertices. By Lemma 4, X must have more than $(1 + \epsilon - \mu)n$ neighbors in R , which implies that some vertices of Y have neighbors in X , a contradiction to the definition of X .

To conclude the proof of Lemma 3, we observe that for $\epsilon < 1/5$, we can take $\delta = 1/3$. Using the fact that $\ln(1 + \epsilon) > \epsilon - \epsilon^2/2$, the requirement of Inequality (2) on d can be seen to be satisfied if $d \geq 5 + 3 \ln(1/\epsilon)$. \square

The following lemma concludes the proof of the expansion property.

Lemma 5. *Let $B(L, R, E)$ be a bipartite graph satisfying the conclusion of Lemma 3. Then, for any integer λ , $1 \leq \lambda \leq \log_{\frac{4}{3}}(\frac{1}{2\epsilon})$, the number of right vertices at augmentation distance at most λ is at least $(1 + (4/3)^\lambda)\epsilon n$.*

Proof. We prove the lemma by induction on λ . We recall that Y_λ denotes the set of right vertices at augmentation distance at most λ . Since the bipartite graph B satisfies the conclusion of Lemma 3, any set of right vertices Y , $\epsilon n \leq |Y| \leq 3n/8$, expands by a factor no less than $4/3$. The lemma holds for $\lambda = 1$, because $|Y_0| = |F| \geq \epsilon n$ and hence, at least $(1 + 4/3)\epsilon n$ right vertices are included in Y_1 .

For some integer λ , $1 \leq \lambda \leq \log_{\frac{4}{3}}(\frac{1}{2\epsilon}) - 1$, let $|Y_\lambda| \geq (1 + (4/3)^\lambda)\epsilon n$. Then, the neighborhood of Y_λ includes at least $(4/3)^{\lambda+1}\epsilon n$ left vertices. Since both the mates of these left vertices and the free vertices are at augmentation distance at most $\lambda + 1$, there are at least $(1 + (4/3)^{\lambda+1})\epsilon n$ right vertices at augmentation distance no greater than $\lambda + 1$, i.e., $|Y_{\lambda+1}| \geq (1 + (4/3)^{\lambda+1})\epsilon n$.

This argument works as long as $\lambda \leq \log_{\frac{4}{3}}(\frac{1}{2\epsilon})$, because the expansion argument works until the size of Y_λ becomes larger than $(1/2 + \epsilon)n$ for the first time. \square

The Shrinking Property. By the expansion property, nearly half of the right vertices are at augmentation distance no greater than $\lambda^* = \lceil \log_{\frac{4}{3}}(\frac{1}{2\epsilon}) \rceil$. The second thing we show is that any set of left vertices X , $|X| \leq \frac{n}{4}$, has at least $2|X|$ neighbors in R whp. (Lemma 7). This

implies that the number of right vertices at augmentation distance greater than $\lambda^* + \lambda$ is at most $2^{-(\lambda+1)} n$. (Lemma 8).

Lemma 6. *Let $d \geq 8$ be an integer. Then, any set of right vertices Y , $|Y| \geq (1/2 + \epsilon)n$, has at least $n - \frac{(1+\epsilon)n - |Y|}{2}$ neighbors, with probability at least $1 - O(n^{4-d})$.*

Proof. We first show the following lemma whose proof is similar to the proof of Lemma 1.

Lemma 7. *Let γ be any positive constant, and let $d \geq (1 + \log e)(2 + \gamma) + \log(1 + \gamma)$ be an integer. Then, any set of left vertices X , $|X| \leq \frac{n}{2(1+\gamma)}$, has at least $(1 + \gamma)|X|$ neighbors with probability at least $1 - O(n^{3+\gamma-d})$.*

Proof. For a fixed integer k , $1 \leq k \leq \frac{n}{2(1+\gamma)}$, let $P(k)$ be the probability that there exists a set of left vertices of size k which does not expand by $(1 + \gamma)$. Then,

$$P(k) \leq \binom{n}{k} \left(\frac{(1+\epsilon)n}{(1+\gamma)k} \right) \left(\frac{(1+\gamma)k}{(1+\epsilon)n} \right)^{dk}.$$

Working similarly to the proof of Lemma 1, we bound $P(k)$ by $O(n^{2+\gamma-d})$ for small values of k , e.g., $1 \leq k \leq \frac{n}{c}$, where c is a sufficiently large positive constant. For $k > \frac{n}{c}$, let $\mu = \frac{k}{n} \in (0, \frac{1}{2(1+\gamma)}]$. Using Proposition 1, we obtain the following lower bound on d .

$$d > 1 + \gamma + \frac{\mu \ln(\frac{1}{\mu}) + (1 - \mu) \ln(\frac{1}{1-\mu}) + (1 + \epsilon - (1 + \gamma)\mu) \ln(\frac{1+\epsilon}{1+\epsilon-(1+\gamma)\mu})}{\mu \ln(\frac{1+\epsilon}{(1+\gamma)\mu})} \quad (3)$$

We observe that the right-hand side of Inequality (3) is maximized for $\mu = \frac{1}{2(1+\gamma)}$ and cannot exceed $(1 + \log e)(2 + \gamma) + \log(1 + \gamma)$. \square

We observe that for $\gamma = 1$, Inequality (3) is satisfied whenever $d \geq 8$. To conclude the proof of Lemma 6, we show that any graph B satisfying the conclusion of Lemma 7 also satisfies the conclusion of Lemma 6. To reach a contradiction, we assume that for some integer k , $0 \leq k \leq \frac{n}{4}$, there is a set of right vertices Y of size $(1 + \epsilon)n - 2k$ with less than $n - k$ neighbors. Let X be the set of left vertices not included in the neighborhood of Y . The size of X must be greater than k . By Lemma 7, X has more than $2k$ neighbors in R , which implies that some vertices of Y have neighbors in X , a contradiction. \square

We observe that for any $\epsilon \in (0, 1/5)$, $5 + 3 \ln(1/\epsilon) \geq 8$ and the hypothesis of Lemma 6 is satisfied by any choice of d satisfying the hypothesis of Theorem 1.

Lemma 8. *Let $B(L, R, E)$ be a bipartite graph satisfying the conclusions of Lemma 3 and Lemma 6 and let $\lambda^* = \lceil \log_{\frac{4}{3}}(\frac{1}{2\epsilon}) \rceil$. Then, for any integer $\lambda \geq 0$, the number of right vertices at augmentation distance greater than $\lambda + \lambda^*$ is at most $2^{-(\lambda+1)} n$.*

Proof. We prove the lemma by induction on λ . By Lemma 5, we know that $|Y_{\lambda^*}| \geq (1/2 + \epsilon)n$. Therefore, for $\lambda = 0$, the number of right vertices at augmentation distance greater than λ^* is at most $n/2$.

For some integer $\lambda \geq 0$, let the number of right vertices at augmentation distance greater than $\lambda + \lambda^*$ be at most $2^{-(\lambda+1)} n$. Consequently, there are at least $(1 + \epsilon - 2^{-(\lambda+1)})n$ right vertices at augmentation distance no greater than $\lambda + \lambda^*$, i.e., $|Y_{\lambda+\lambda^*}| \geq (1 + \epsilon - 2^{-(\lambda+1)})n$. By Lemma 8, the neighborhood of $Y_{\lambda+\lambda^*}$ includes at least $(1 - 2^{-(\lambda+2)})n$ left vertices. Both the mates of these left vertices and the free vertices are at augmentation distance at most $(\lambda+1) + \lambda^*$. Hence, $|Y_{(\lambda+1)+\lambda^*}| \geq (1 + \epsilon - 2^{-(\lambda+2)})n$, and no more than $2^{-(\lambda+2)} n$ right vertices are at augmentation distance greater than $(\lambda+1) + \lambda^*$. \square

Bounding the Size of the BFS Tree. Let v be a newly arrived left vertex, and let T_v be the random variable denoting the number of right vertices encountered before a shortest augmenting path starting at v is found (i.e., before the BFS reaches the first free vertex). Clearly, the insertion algorithm can add v to the current matching in $O(T_v)$ time and space. Then, we use the assumption that the current matching and the sets Y_λ do not depend on the random choices of v , and we show that (i) T_v does not exceed $o(n)$ whp. and (ii) the expectation of T_v does not exceed $2d^{\lambda^*+2}$.

We first assume that the bipartite graph B satisfies the conclusions of Lemma 3 and Lemma 6 and contains an L -perfect matching which covers v . In addition, we assume that no rehash is carried out if there are too many right vertices in the BFS tree.

If at least one of the d neighbors of v is at augmentation distance at most λ , an augmenting path is found after at most $d^{\lambda+1}$ right vertices have been visited. Therefore, for any integer $\lambda \geq 0$, the probability that T_v exceeds $d^{\lambda+1}$ is at most $(1 - \frac{|Y_\lambda|}{(1+\epsilon)n})^d$.

By Lemma 8, there are at most $2^{-(\lambda+1)} n$ right vertices at augmentation distance greater than $\lambda + \lambda^*$. Hence, $1 - \frac{|Y_{\lambda^*+\lambda}|}{(1+\epsilon)n} \leq 2^{-(\lambda+1)}$. Let $\beta > 0$ be any constant in the interval $(0, 1/2)$. Then,

$$\Pr[T_v > d^{\lambda^*+1} n^{1-\beta}] < 2^{-(1-\beta)d \log_d n} = n^{-(1-\beta)d/\log d}.$$

Using $\beta = 9/10$ and $d \geq 8$, we conclude that the probability that more than $d^{\lambda^*+1} n^{9/10}$ right vertices are encountered before an augmenting path is found does not exceed $n^{-24/10}$. In addition, for $d \geq 8$, the bipartite graph B violates the conclusions of Lemma 3 or Lemma 6 with probability $O(n^{-4})$, and B does not contain an L -perfect matching with probability $O(n^{-12})$.

As for the expectation of T_v ,

$$\begin{aligned} \mathbb{E}[T_v] &= \sum_{t=1}^{\infty} \Pr[T_v \geq t] \\ &\leq d + \sum_{\lambda=0}^{\infty} d^{\lambda+2} \Pr[v \text{ has no neighbor in } Y_\lambda] \\ &\leq d + \sum_{\lambda=0}^{\infty} d^{\lambda+2} \left(1 - \frac{|Y_\lambda|}{(1+\epsilon)n}\right)^d \\ &\leq d^{\lambda^*+2} + \frac{d^{\lambda^*+2}}{2^d} \sum_{\lambda=0}^{\infty} \left(\frac{d}{2^d}\right)^\lambda, \end{aligned}$$

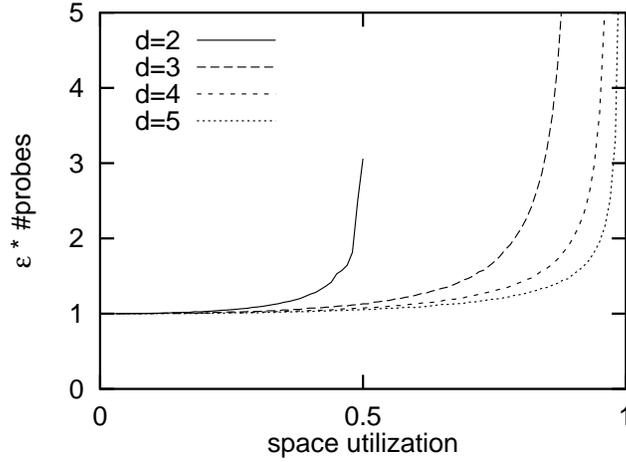

Fig. 2. Scaled average number of memory probes for insertion into a d -ary Cuckoo Hash table with 100 000 entries as a function of the memory utilization $n/10^5$ ($\epsilon = 1 - n/10^5$). Starting from $n = 1000 \cdot k$ ($k \in \{1, \dots, 100\}$), a random element is removed and a new random element is inserted. This is repeated 1000 times for each of 100 independent runs. Hash functions are full lookup tables filled with random elements generated using [18]. The curves stop when any insertion fails after 1000 probes.

where the last inequality follows from Lemma 8. For any $d \geq 8$, $d/2^d \leq 1/32$ and the above sum can be bounded by $\frac{249}{248} d^{\lambda^*+2}$.

We have also to consider the contribution of several low probability events to the expectation of T_v . For $d \geq 8$, more than $d^{\lambda^*+1} n^{9/10}$ right vertices are encountered before an augmenting path is found with probability $O(n^{-24/10})$, the bipartite graph B violates the conclusions of Lemma 3 or Lemma 6 with probability $O(n^{-4})$, and B does not contain an L -perfect matching with probability $O(n^{-12})$. Each of these events causes a rehash, whose cost is bounded by $O(n^2)$. Therefore, these low probability events have a negligible contribution to the expectation of T_v , which can be bounded by $2 d^{\lambda^*+2}$.

We can choose $d = \Theta(\ln \frac{1}{\epsilon})$. Using $\lambda^* = \Theta(\ln \frac{1}{\epsilon})$, we conclude that the expectation of T_v is $(1/\epsilon)^{O(\ln d)}$. \square

4 Experiments

Our theoretical analysis is not tight with respect to the constant factors and lower order terms in the relation between the worst case number of probes d and the waste of space ϵn . The analysis is even less accurate with respect to the insertion time. Since these quantities are important to judge how practical d -ary Cuckoo Hashing might be, we designed an experiment that can partially fill this gap. We decided to focus on a variant that looks promising in practice: We use d separate tables of size $(1 + \epsilon)n/d$ because then it is not necessary to reevaluate the hash function that led to the old position of an element to be moved. Insertion uses a random walk, i.e., an element to be allocated randomly picks one of its d choices even if the space is occupied. In the latter case, the displaced element randomly picks one of its

$d - 1$ remaining choices, etc., until a free table entry is found. The random walk insertion saves us some bookkeeping that would be needed for insertion by BFS. Figure 2 shows the average number of probes needed for insertion as a function of the space utilization $1/(1 + \epsilon)$ for $d \in \{2, 3, 4, 5\}$. Since $1/\epsilon$ is a lower bound, the y -axis is scaled by ϵ . We see that all schemes are close to the insertion time $1/\epsilon$ for small utilization and grow quickly as they approach a capacity threshold that depends on d . Increasing d strictly decreases expected insertion time so that we get clear trade-off between worst case access time guarantees and average insertion time.

The maximum space utilization approaches one quickly as d is incremented. The observed thresholds were at 49 % for $d = 2$, 91 % at $d = 3$, 97 % at $d = 4$, and 99 % at $d = 5$.

5 Filter Hashing

In this section, we describe and analyze *Filter Hashing*, a simple hashing scheme with worst case constant lookup time, that can be used in combination with essentially any other hashing scheme to improve the space efficiency of the latter. More precisely, Filter Hashing space efficiently stores almost all elements of a set. The remaining elements can then be stored using a less space efficient hashing scheme, e.g., [7].

To explain Filter Hashing, we again switch to the terminology of bipartite graphs. For a parameter γ , $0 < \gamma < 1$ we split the right vertices into $d = \Theta(\ln^2(1/\gamma))$ parts, called *layers*, of total size at most n . Each left vertex is associated with exactly one neighbor in each of the d layers, using hash functions as described below. A newly arrived vertex is always matched to an unmatched neighbor in the layer with the *smallest possible* number. The name filter hashing comes from the analogy of a particle (hash table element / left vertex) passing through a cascade of d filters (layers). If all the neighbors in the d layers have been matched, the vertex is not stored, i.e., it is left to the hashing scheme handling such “overflowing” vertices. We will show that this happens to at most γn elements whp.

If the hashing scheme used for the overflowing vertices uses linear space, a total space usage of $(1 + \epsilon)n$ cells can be achieved for $\gamma = \Omega(\epsilon)$. For example, if we use the dictionary of [7] to handle overflowing vertices, the space used for overflowing vertices is $O(\gamma n)$, and every insertion and lookup of an overflowing vertex takes constant time whp. Even though this scheme exhibits relatively high constant factors in time and space, the effect on space and average time of the combined hashing scheme is small if we choose the constant γ to be small.

A hashing scheme similar to filter hashing, using $O(\log \log n)$ layers, was proposed in [2], but only analyzed for load factor less than $1/2$. Here, we use stronger tools and hash functions to get an analysis for load factors arbitrarily close to 1.

What happens in the filtering scheme can be seen as letting the left vertices decide their mates using a multi-level balls and bins scenario, until the number of unmatched left vertices becomes small enough. The scheme gives a trade-off between the number of layers and the fraction γ of overflowing vertices.

We proceed to describe precisely the bipartite graph $B(L, R, E)$ used for the scheme, where $|L| = |R| = n$. We partition R into d layers R_i , $i = 1 \dots d$, where $d = \lceil \ln^2(4/\gamma) \rceil$ and $|R_i| = \left\lfloor \frac{n}{\ln(4/\gamma)} \left(1 - \frac{1}{\ln(4/\gamma)}\right)^{i-1} \right\rfloor$. Suppose that $L \subseteq \{1, \dots, m\}$ for some integer m , or, equivalently, that we have some way of mapping each vertex to a unique integer in $\{1, \dots, m\}$. The edges connecting a vertex $v \in L$ to R_i , for $i = 1, \dots, d$, are given by function values on v of the hash functions

$$h_i(x) = \left(\sum_{j=0}^t a_{ij} x^j \bmod p \right) \bmod |R_i| \quad (4)$$

where $t = 12 \lceil \ln(4/\gamma) + 1 \rceil$, $p > mn$ is a prime number and the a_{ij} are randomly and independently chosen from $\{0, \dots, p-1\}$.

For n larger than a suitable constant (depending on d), the total size $\sum_{i=1}^d |R_i|$ of the d layers is in the range

$$\begin{aligned} & \left[\sum_{i=1}^d \frac{n}{\ln(4/\gamma)} \left(1 - \frac{1}{\ln(4/\gamma)}\right)^{i-1} - d ; \sum_{i=1}^{\infty} \frac{n}{\ln(4/\gamma)} \left(1 - \frac{1}{\ln(4/\gamma)}\right)^{i-1} \right] \\ & = \left[n \left(1 - \left(1 - \frac{1}{\ln(4/\gamma)}\right)^d\right) - d ; n \right] \subseteq \left[\left(1 - \frac{\gamma}{2}\right) n ; n \right] \end{aligned}$$

From the description of filter hashing, it is straightforward that the worst case insertion time and the worst case access time are at most d . In the following, we prove that at most γn left vertices overflow whp., and that the average time for a successful search is $O(\ln(1/\gamma))$. Both these results are implied by the following lemma.

Lemma 9. *For any constant γ , $0 < \gamma < 1$, for $d = \lceil \ln^2(4/\gamma) \rceil$ and n larger than a suitable constant, the number of left vertices matched to vertices in R_i is at least $(1 - \gamma/2)|R_i|$ for $i = 1, \dots, d$ with probability $1 - O\left(\left(\frac{1}{\gamma}\right)^{O(\log \log(\frac{1}{\gamma}))} \frac{1}{n}\right)$.*

Proof. We use tools from [8] to prove that each of the layers has at least a fraction $(1 - \gamma/2)$ of its vertices matched to left vertices with probability $1 - O\left(\left(\frac{1}{\gamma}\right)^{O(\log \log(\frac{1}{\gamma}))} \frac{1}{n}\right)$. As there are $O(\ln^2(1/\gamma))$ layers, the probability that this happens for all layers is also $1 - O\left(\left(\frac{1}{\gamma}\right)^{O(\log \log(\frac{1}{\gamma}))} \frac{1}{n}\right)$.

The number of left vertices that are not matched to a vertex in layers R_1, \dots, R_{i-1} is at least $n_i = n - \sum_{j=1}^{i-1} |R_j|$. We have the inequalities $(1 - \frac{1}{\ln(4/\gamma)})^{i-1} n \leq n_i \leq (1 - \frac{1}{\ln(4/\gamma)})^{i-1} + i$. Consider the random variable $\text{free}(R_{i+1})$ denoting the number of empty bins in the balls and bins scenario with n_{i+1} balls and $|R_{i+1}|$ bins, where the positions of the balls are given by a hash function of the form (4). This is a pessimistic estimate of the number of free vertices in layer $i+1$ of the hashing scheme, since n_{i+1} is a lower bound on the number vertices that are not matched to R_1, \dots, R_i . We use tools for analyzing such a scenario from [8] to show that $\text{free}(R_{i+1}) \leq \frac{\gamma}{2}|R_{i+1}|$ with probability $1 - O(\frac{1}{n})$. Denote by b_j the number of balls in bin

number j and let $C_k = \sum_{j=1}^{|R_{i+1}|} \binom{b_j}{k}$ be the number of “colliding k -sets of balls”. Since $t/2$ is even, we have the following inequality [8, Proposition 6]:

$$\text{free}(R_{i+1}) \leq \sum_{k=0}^{t/2} (-1)^k C_k \quad (5)$$

The “load factor” of the balls and bins scenario is $\alpha = n_{i+1}/|R_{i+1}| \geq \ln(4/\gamma)$. Since $p > mn$ we get from [8] that for $k \leq t/2$,

$$(1 - O(\frac{1}{n_{i+1}})) n_{i+1} \alpha^{k-1} / k! \leq \mathbb{E}[C_k] \leq (1 + O(\frac{1}{n_{i+1}})) n_{i+1} \alpha^{k-1} / k! .$$

Thus we get the following upper bound:

$$\mathbb{E}[\text{free}(R_{i+1})] \leq (1 + O(\frac{1}{n_{i+1}})) n_{i+1} \sum_{k=0}^{t/2} (-1)^k \alpha^{k-1} / k! \leq \frac{3}{2} n_{i+1} e^{-\alpha} / \alpha \leq \frac{3\gamma}{8} |R_{i+1}| \quad (6)$$

where the second inequality uses $t \geq 10\alpha$ and that n (and thus n_{i+1}) is sufficiently large.

It is shown in [8] that $\text{Var}(C_k) = O(\alpha^{2k} n)$ for $k \leq t/2$. Thus we can use Chebychev’s inequality to bound the probability that $\text{free}(R_{i+1})$ exceeds $\frac{\gamma}{2} |R_{i+1}|$:

$$\begin{aligned} \Pr[\text{free}(R_{i+1}) > \frac{\gamma}{2} |R_{i+1}|] &\leq \sum_{k=0}^{t/2} \Pr[|C_k - \mathbb{E}[C_k]| > \frac{\gamma}{8} |R_{i+1}| / (t/2 + 1)] \\ &\leq \sum_{k=0}^{t/2} \text{Var}(C_k) / (\frac{\gamma}{8} |R_{i+1}| / (t/2 + 1))^2 \\ &= O\left(\left(\frac{1}{\gamma}\right)^{O(\log \log(\frac{1}{\gamma}))} \frac{1}{n}\right) . \end{aligned}$$

□

Lemma 9 implies that there are at most $\frac{\gamma}{2} n$ of the n right side vertices that are not part of R_1, \dots, R_d , and with probability $1 - O(\frac{1}{n})$ there are at most $\frac{\gamma}{2} n$ vertices in the layers that are not matched. Thus, with probability $1 - O(\frac{1}{n})$ no more than γn vertices overflow.

The expected average time for a successful search can be bounded as follows. The number of elements with search time $i \leq d$ is at most $|R_i|$, and the probability that a random left vertex overflows is at most $\gamma + O(\frac{1}{n})$, i.e., the expected total search time for all elements is bounded by:

$$\begin{aligned} (\gamma + O(\frac{1}{n})) nd + \sum_{i=1}^d |R_i| i &\leq (\gamma + O(\frac{1}{n})) \left\lceil \ln^2(\frac{4}{\gamma}) \right\rceil n + \frac{n}{\ln(\frac{4}{\gamma})} \sum_{i=0}^{\infty} \left(1 - \frac{1}{\ln(\frac{4}{\gamma})}\right)^i i \\ &= O(n \ln(\frac{4}{\gamma})) . \end{aligned}$$

The expected time to perform a rehash in case too many elements overflow is $O(\ln(1/\gamma) n)$. Since the probability that this happens for any particular insertion is $O((\frac{1}{\gamma})^{O(\log \log(\frac{1}{\gamma}))} \frac{1}{n})$, the expected cost of rehashing for each insertion is $(\frac{1}{\gamma})^{O(\log \log(\frac{1}{\gamma}))}$. Rehashes caused by the total number of elements (including those marked deleted) exceeding n have a cost of $O(\ln(\frac{1}{\gamma})/\gamma)$ per insertion and deletion, which is negligible.

6 Conclusions and Open Problems

From a practical point of view, d -ary Cuckoo Hashing seems a very advantageous approach to space efficient hash tables with worst case constant access time. Both worst case access time and average insertion time are very good. It also seems that one could make *average* access time quite small. A wide spectrum of algorithms could be tried out from maintaining an optimal placement of elements (via minimum weight bipartite matching) to simple and fast heuristics.

Theoretically, there are two main open questions. The first concerns tight (high probability) bounds for the insertion time. The second question is whether the analysis of d -ary Cuckoo Hashing also works for practical, constant time evaluable hash functions. Dietzfelbinger has suggested [6] the following interesting solution: A very simple hash function based on polynomials of constant degree is used to partition the elements into $\log n$ disjoint groups of size at most $\frac{(1+\epsilon/2)n}{\log n}$ [15]. Now space linear in the size of one group ($O(dn/\log n)$) is invested to obtain an emulation of d uniform hash functions within one group. This can be achieved using recent constructions by Pagh and Östlin [21], or Dietzfelbinger and Wölfel [10]. Each group is stored in a table with $\frac{(1+\epsilon)n}{\log n}$ entries. The main trick is that the same d hash functions can be used for *all* the groups so that the total space needed for the hash functions remains sublinear.

Filter Hashing is inferior in practice to d -ary Cuckoo Hashing but it might have specialized applications. For example, it could be used as a *lossy* hash table with worst case constant *insertion* time. This might make sense in real time applications where delays are not acceptable whereas losing some entries might be tolerable, e.g., for gathering statistic information on the system. In this context, it would be theoretically and practically interesting to give performance guarantees for simpler hash functions.

A Appendix

A.1 Proof of Proposition 2

There are several cases to consider. We first distinguish between $\mu \leq \frac{1}{2}$ and $\mu > \frac{1}{2}$.

Case A. $\mu \in (0, \frac{1}{2}]$. Then, for all $\epsilon \in (0, 1)$,

$$\frac{(1 - \mu) \ln\left(\frac{1}{1 - \mu}\right)}{\mu \ln\left(\frac{1 + \epsilon}{\mu}\right)} \leq \frac{(1 - \mu) \ln\left(\frac{1}{1 - \mu}\right)}{\mu \ln\left(\frac{1}{\mu}\right)} \leq 1 \leq \frac{\epsilon \ln\left(\frac{1 + \epsilon}{\epsilon}\right)}{\ln(1 + \epsilon)} .$$

Case B. $\mu \in (\frac{1}{2}, 1]$. We distinguish between $\epsilon \geq \frac{1}{e}$ and $\epsilon < \frac{1}{e}$.

Case B.1. $\epsilon \geq \frac{1}{e}$. We first observe that $\mu \ln\left(\frac{1 + \epsilon}{\mu}\right) \geq \ln(1 + \epsilon)$, for all $\mu \in (\frac{1}{2}, 1]$ and $\epsilon \in (0, 1)$. Then, the claim follows from

$$(1 - \mu) \ln\left(\frac{1}{1 - \mu}\right) \leq \frac{1}{e} < \frac{\ln(e + 1)}{e} \leq \epsilon \ln\left(\frac{1 + \epsilon}{\epsilon}\right) .$$

Case B.2. $\epsilon \in (0, \frac{1}{e})$. We consider the following cases:

Case B.2.i. $\mu \in (1 - \epsilon, 1]$. Then $1 - \mu < \epsilon < \frac{1}{e}$. Since the function $x \ln(\frac{1}{x})$ is non-decreasing in the interval $[0, \frac{1}{e})$, we conclude that $(1 - \mu) \ln(\frac{1}{1 - \mu}) \leq \epsilon \ln(\frac{1}{\epsilon})$. In addition, as in B.1., $\mu \ln(\frac{1 + \epsilon}{\mu}) \geq \ln(1 + \epsilon)$, and the claim follows.

Case B.2.ii. $\mu \in (\frac{1}{2}, 1 - \epsilon]$. Since the function $\frac{(1 - \mu) \ln(\frac{1}{1 - \mu})}{\mu \ln(\frac{1}{\mu})}$ is non-decreasing, we obtain that

$$\frac{(1 - \mu) \ln(\frac{1}{1 - \mu})}{\mu \ln(\frac{1 + \epsilon}{\mu})} \leq \frac{(1 - \mu) \ln(\frac{1}{1 - \mu})}{\mu \ln(\frac{1}{\mu})} \leq \frac{\epsilon \ln(\frac{1}{\epsilon})}{(1 - \epsilon) \ln(\frac{1}{1 - \epsilon})} \leq \frac{\epsilon \ln(\frac{1 + \epsilon}{\epsilon})}{\ln(1 + \epsilon)} ,$$

where the last inequality holds for all $\epsilon \in (0, 1)$. □
