Abstract

We suggest the use of an Internet job-search indicator (the Google Index, GI) as the best leading indicator to predict the US unemployment rate. We perform a deep out-of-sample forecasting comparison analyzing many models that adopt both our preferred leading indicator (GI), the more standard initial claims or combinations of both. We find that models augmented with the GI outperform the traditional ones in predicting the monthly unemployment rate, even in most state-level forecasts and in comparison with the Survey of Professional Forecasters.

Keywords: Google econometrics, Forecast comparison, Keyword search, US unemployment, Time series models.

1 Introduction

Quantitative data on internet use are becoming quickly available and will constitute an invaluable source for economic analysis in the near future. Following the growing popularity of the internet as a job search tool and the increasing need of reliable and updated unemployment forecasts, especially in the recent economic downturn, in this article we suggest the use of the Google index (GI) as the best leading indicator to predict the US unemployment rate.¹ We test the predictive power of this new leading indicator based on Google job-search-related query data by means of a deep out-of-sample comparison among more than five hundred forecasting models which differ along three dimensions: i) the exogenous variables adopted as leading indicators, ii) the econometric specification, and iii) the length of the estimation sample. In particular, we estimate standard time series (ARMA) models and we augment them with the initial claims (the IC, a widely accepted leading indicator for the US unemployment rate), the GI, or combinations of both. In carrying out our comparison, we include both linear and non-linear models, because the former typically capture short-run developments, while the latter can better approximate the dynamics of the unemployment rate during economic contractions. In our forecasting horse-race, we compare models estimated over samples of different length, because the GI is only available since 2004, while the IC are available since 1967. Indeed, an exercise comparing the forecasting performance of models estimated on the short sample only (starting in 2004) would be of little practical relevance if models estimated on the longer sample (starting in 1967) were better at predicting the unemployment rate.

We find that models augmented with the GI significantly outperform the more traditional ones in predicting the US unemployment rate: when forecasting at one-step ahead

¹The time series of US unemployment rate is certainly one of the most studied in the literature. Proietti (2003) defines this series as the ‘testbed’ or the ‘case study’ for many (if not most) non-linear time series models. In fact, many papers have documented its asymmetric behavior. Neftci (1984), DeLong and Summers (1986) and Rothman (1998) document the type of asymmetry called *steepness* for which unemployment rates rise faster than they decrease. Sichel (1993) finds evidence for another type of asymmetry called *deepness* in which contractions are deeper than expansions. McQueen and Thorley (1993) find *sharpness* for which peaks tend to be sharp while troughs are usually more rounded.

the mean squared error (MSE) of our best model using GI as a leading indicator (0.0166) is 29% lower than the best model not including it, regardless of the estimation sample and the econometric specification. Relative forecast accuracy increases at longer forecast horizons: at three steps ahead, when using the GI the MSE decreases by 40%.

As a robustness check, we test the predictive power of the GI estimating the same set of models on the most commonly used transformations for the time series of the unemployment rate,² finding similar results. As a further check, we forecast the unemployment rate in each of the 51 US states (including District of Columbia) with the same set of models, finding that in more than 70% of the cases, models including the GI outperform all the others. Finally, we construct a group of quarterly forecasts of the unemployment rate using the best models from our horse-race and compare them with the quarterly predictions released by the Survey of Professional Forecasters (SPF), conducted by the Federal Reserve Bank of Philadelphia. Even in this case we find that models using the GI outperform the professionals' forecasts, showing a lower MSE by an order of magnitude.

Furthermore, we select the best models in terms of the lowest MSE and we test both for equal forecast accuracy and forecast encompassing to assess their out-of-sample forecast ability. We also test our best models in terms of their superior predictive ability, which allows us to control for the effects of data-snooping biases. To do this we employ the Reality Check test suggested by White (2000).

The first article using Google data (Ginsberg et al., 2009) estimates the weekly '*influenza*' activity in the US using an index of the health seeking behavior equal to the incidence of *influenza*-related internet queries. To the best of our knowledge, this is the first paper using this kind of internet indicator to forecast the unemployment rate in the US. However, there have already been some works for other countries, in particular for Germany (Askatas and Zimmermann, 2009), Italy (D'Amuri, 2009) and Israel (Suhoy, 2009), while Choi and Varian (2009) use the GI to predict initial unemployment claims

²In particular, we use the following transformations: logit (as in Koop and Potter, 1999 or Wallis, 1987), first differences (as in Montgomery et al, 1998), logarithm, log-linear detrended or HP-filtered in logs (as in Rothman, 1998).

for the US. Based on our results for the unemployment rate, we believe that there will be more and more applications using Google query data in the future also in other fields of economics.

The paper is organized as follows: in Section 2 we describe the data used to predict the US unemployment rate, with a particular emphasis on the Google index. In Section 3 we discuss the models employed to predict the US unemployment rate, while in Section 4 we compare the out-of-sample performance of such models. Finally, in Section 5 we perform some robustness tests, checking the predictive ability of models augmented with the GI at the state level, comparing the results of the federal estimates both with the quarterly estimates of the SPF and some nonlinear models typically deemed as the best forecasting models in the literature. In section 6 we present our conclusions.

2 Data

The data used in this paper come from different sources. The seasonally adjusted monthly unemployment rate is the one released by the Bureau of Labor Statistics and comes from the Current Employment Statistics and the Local Area Unemployment Statistics for the national and the state level, respectively. Unemployment rates for month t refer to individuals who do not have a job, but are available for work, in the week including the 12th day of month t and who have looked for a job in the prior 4 weeks ending with the reference week. For the federal level the available sample is 1948.1-2009.6, while for the state level the data on unemployment are available from 1976.1 to 2009.6. We complement these data with the weekly seasonally adjusted Initial Claims (IC) released by the U.S. Department of Labor³, a well-known leading indicator for the unemployment rate (see for example Montgomery et al. 1998). The weekly IC for the US are available from 1967.1 until 2009.6, while for the single states they are only available from 1986.12.

The exogenous variable specific to this study is the weekly Google Index (GI) which

³Since seasonally adjusted data are issued only at the national level, we have performed our own seasonal adjustment for the state-level data using Tramo-Seats.

summarizes the job searches performed through the Google website. The data are available almost in real time starting with the week ending on January 10, 2004 and report the incidence of queries using the keyword “*jobs*” on total queries performed through Google in the relevant week.⁴ The values of the index, available free of charge,⁵ are normalized with a value equal to 100 for the week with the highest incidence.

We chose to use the keyword “*jobs*” as an indicator of job search activities for two reasons. First, since absolute search volumes are not available, we identify the most popular keywords looking at relative incidences. In these terms, we found that the keyword “*jobs*” was the one showing the highest incidence among different job-search-related keywords. Even if we do not know the absolute search volumes, we can compare the relative incidences of searches for the keyword “*jobs*” with other extremely popular keywords searches. In particular, in Figure 1, we plot the monthly averages for the values of the GI for the keywords: “*facebook*”, “*youtube*”, “*jobs*” and “*job offer*”. We notice that, when the incidence of keyword searches for “*facebook*” was at its highest level in the interval considered here, the GI was slightly below the value of 80, while the GI for the keyword “*jobs*” was slightly above 20. This means that in that period there was more than one keyword search for “*jobs*” for each four searches for “*facebook*”. The results are similar when conducting the comparison with the keyword “*youtube*”, another popular search. Finally, the alternative job-search-related keyword “*job offers*” reaches very low values of the GI (basically zero) in the interval. Apart from its popularity, the second reason why we chose the keyword “*jobs*” is that we believe that it is widely used across the broadest range of job seekers. We could have augmented it with other job-search-related keywords, such as “*unemployment benefits*” or “*state jobs*”. This would have increased the volume of searches underlying the value of the GI. But, at the same time, the information conveyed by these keywords is related to particular subgroups of the population, and the presence of demand or supply shocks specific to these subgroups could bias the values of the GI and its ability to predict the overall unemployment rate.

⁴We have adjusted both the weekly and the monthly indicators for seasonality using Tramo-Seats.

⁵www.google.com/insights/search/#. The data used in this article were downloaded on July 29, 2009.

However, the variable has its limitations: individuals looking for a job through the internet (jobs available through the internet) may well be not randomly selected among job seekers (jobs). Moreover, the indicator captures overall job search activities, that is the sum of searches performed by unemployed and employed people. This limitation is made more severe by the fact that, while unemployed's job search is believed to follow the anti-cyclical variation of job separation rates, on-the-job search is normally assumed to be cyclical. We acknowledge that this can induce some bias in our preferred leading indicator the GI.

In the empirical analysis we align the GI and IC data with the relevant weeks for the unemployment survey. In other words, when constructing the GI or the IC for month t , we take into consideration the week including the 12th of the month and the three preceding weeks, exactly the same interval used to calculate the unemployment rate for month t reported in official statistics. When there are more than four weeks between the reference week of month t and the following one in month $t + 1$, we do not use either the GI or the IC for the week that is not used by the official statistics in order to calculate the unemployment rate (see Figure 2 for a visual description of the alignment procedure).

Table 1 reports the descriptive statistics for various transformations of the US unemployment rate and both leading indicators (IC and the GI, both weekly and monthly). In the Appendix we also show the descriptive statistics of the IC and the GI both for the United States as a whole and for each single state (Tables A.1, A.2 and A.3). The IC for the US are publicly available through the Department of Labor website starting with January 1967, while those for the single states are available since December 1986. The monthly averages of the IC have almost always right-skewed distributions and are highly non-normal (we always reject the null of normality with the Jarque-Bera test). The monthly averages of the GI (which starts in January 2004) are also right-skewed with non-normal distribution, except for Alaska and Maine. The weekly IC and GI (those with the subscript $wj, j = 1, \dots, 4$) show similar features. From Table A.4 in the Appendix we can infer that the unemployment rate also has a right-skewed distribution and a high kur-

tosis which make the series non-normal as suggested by the Jarque-Bera test that almost always rejects the null hypothesis of normality. The same happens for the unemployment rate of each single state except for Colorado.

In Figure 3 and 4, we plot separately the national unemployment rate and our exogenous variables adopted as leading indicators over the relevant sample periods. In Figure 3, we plot the unemployment rate and the IC over the sample period 1967:1-2009:6, according to the availability of IC. Figure 4 depicts instead the unemployment rate along with the IC as well as the Google ‘job’ search index over the sample 2004:1-2009:6. These latter indexes are rescaled with respect to the maximum value of each series over the sample. In both cases the two series show similar patterns, with both IC and the GI seeming to be leading indicators for the unemployment rate. This behavior is confirmed by the correlations: focusing on the 2004:1-2009:6 period, we can see that both the GI and the IC are highly correlated with the level and with the first differences of the unemployment rate (see Table 2). In particular, the correlations of the GI with the first differences are higher than those of the IC, suggesting that this alternative indicator can be rather helpful for predicting not only the level of the unemployment rate but also its changes.

Before proceeding with our forecasting exercise and the in-sample estimation of our set of models, we have checked for non-stationarity of the US unemployment rate by computing a robust univariate unit root test for the integration of the series. We have performed the Augmented Dickey-Fuller test with GLS de-trending (ADF-GLS) suggested by Elliott et al. (1996). This test is similar to the more standard Dickey-Fuller t test but it applies GLS de-trending before the series is tested with the ADF test. Compared with the standard ADF test, ADF-GLS test has the best overall performance in terms of small-sample size and power. Table 3 reports the results of this unit root test both considering a constant (superscript μ) and a constant and trend (superscript τ) as exogenous regressors. We run these tests both for the full sample, i.e. 1967.1-2009.6, and for the short sample, i.e. 2004.1-2009.6. We report the unit root test results for the unemployment rate in

levels u_t , and for other transformations typically used in the literature on the US.⁶

Looking at u_t , the ADF-GLS ^{μ} test fails to reject the null of a unit root for the full sample, but strongly rejects (at 1%) the null for the short sample. Similarly, the ADF-GLS ^{τ} test fails to reject the null of a unit root on the full sample but it does reject the null on the short sample, indicating that the series of unemployment is stationary over this shorter sample. For all the other transformations, the ADF-GLS tests suggest an overall rejection of the null of a unit root only when the null is non-stationarity around the mean over the short sample. The test fails to reject over the full sample, except for the transformation u_t^{LHP} . We should also notice that over the short sample the ADF-GLS ^{τ} tests are very close to the 10% critical value.

However, in the literature most works impose the presence of a unit root using the first differences of the unemployment rate for forecasting purposes. For example, Montgomery et al. (1998) argue that unit-root non-stationarity might be hard to justify for the US unemployment rate series, but nevertheless adopt an ARIMA(1,1,0)(4,0,4) as their benchmark model for short-term forecasting. In what follows, we adopt a more general approach modeling both the level and the first differences of the unemployment rate series because we are interested in finding the best model for short-term forecasting and not in modeling the long-term dynamics of the series.

3 Forecasting models

In our forecasting exercise we compare a total of 520 linear ARMA models for the variable $u_t - u_{t-1}$, which denotes the first differences of the US unemployment rate. As a robustness check, we also estimate the same set of models on the level and the most commonly used transformations for u_t : logarithm, logit, first differences, log-linear detrended or HP-filtered in logs. For the sake of brevity, and since all main results are confirmed when

⁶We use in particular, the log-level ($\log(u_t)$), the logistic transformation ($u_t^{logit} = \log(\frac{u_t}{1-u_t})$) suggested by Koop and Potter (1999) following Wallis (1987) to make the series unbounded, the log-linear de-trended ($u_t^{LLD} = \log(u_t) - \hat{a} - \hat{b}t$) and the HP-filtered series in log (u_t^{LHP}) both suggested by Rothman (1998).

using these transformations, we will only comment on the estimates obtained from the first differences of the unemployment rate. A full list of the models estimated on this series and their forecasting performance can be found in Table A.5 of the Appendix.

We estimate 384 AR, ARMA and ARMAX models that can be grouped in three broad categories:

- a) models *not including* the GI as an exogenous variable and estimated on the full sample (in sample 1967:1-2007:2; out of sample 2007:3-2009.6)
- b) models *not including* the GI as an exogenous variable but estimated on the short sample, for which Google data are available (in sample 2004:1-2007:2; out of sample 2007:3-2009.6)
- c) models *including* the GI as an exogenous variable and estimated on the short sample (in sample 2004:1-2007:2; out of sample 2007:3-2009.6).

Within these three broad groups we estimate exactly the same set of models, both in terms of lag specification and of exogenous variables included, with the GI indicator added as an additional independent variable in the last, otherwise identical, set of models.

We also estimate, on the short sample, an additional set of 136 models including different combinations of lag structures and exogenous variables. The rationale of repeating our forecasting exercise along three dimensions is straightforward. The inclusion of the GI among the exogenous variables limits the length of the estimation interval, given that the indicator is available only since 2004.1. An exercise comparing the forecasting performance of models estimated on samples starting in 2004:1 could be able to assess the predictive power of the GI, but it would be of little practical relevance if models estimated on the longer sample were better at predicting unemployment rate dynamics.

Within the three groups we estimate pure time series $AR(p)$ and $ARMA(p, q)$ models, with at most 2 lags for p and q , for a total of four models ($AR(1)$, $AR(2)$, $ARMA(1,1)$ and $ARMA(2,2)$).

In addition, we augment these basic specifications with exogenous leading indicators, i.e. ARMAX(p, q):

$$\phi(L)u_t = \mu + x_t'\beta + \theta(L)\varepsilon_t \quad (1)$$

where x_t' is a vector with a first column of ones and one or more columns of leading indicators. These indicators should help improving the predictions of the US unemployment rate.

In particular, we use as exogenous variables (both on the short and the long sample) the monthly IC, i.e. IC_t , their weekly levels ($IC_{w1,t}$, $IC_{w2,t}$, $IC_{w3,t}$, and $IC_{w4,t}$) and their lags up to the second. We then estimated the same models for the short sample using the monthly average of the GI (G_t), its weekly values ($G_{w1,t}$, $G_{w2,t}$, $G_{w3,t}$, and $G_{w4,t}$) and their lags up to the second. Additionally, we augmented the four models with both leading indicators combined at the same frequency either monthly or weekly, at the same month t and for the previous months up to the second. Finally, the four models are estimated with both indicators, IC and the GI, both monthly and for each week. All these models are estimated adding seasonal multiplicative factors.⁷ In Table 4, we summarize all the groups of models within the short and the full sample.⁸

In our pseudo-out-of-sample exercise we consider the situation that real forecasters face when they produce their forecasts and the future values of the exogenous variables (x_t) need to be forecast. At any given date, we have run our forecasting horse-race using only the information that was really available at that time. Therefore, we have adopted simple ARMA models to predict x_t , so that we could use such predictions as inputs in our forecasting models. For robustness, we have considered different models⁹ but we present only those using an AR(1).

⁷In particular, we used a seasonal multiplicative autoregressive factor $SAR(12)$ for AR models and both an AR and MA seasonal $SMA(12)$ for ARMA models.

⁸In all our forecasting exercises we use a rolling window. However we have also performed our forecasting horse-race using a recursive scheme. The results are similar to those with a rolling scheme and are not reported for the sake of brevity, but they are available upon request.

⁹We have adopted an AR(1), AR(2), ARMA(1,1) and ARMA(2,2) and the results are quite similar.

4 Out-of-Sample Forecasting Comparison

When we perform an out-of-sample forecasting horse-race comparing numerous models it is extremely important to assess which model has the highest forecast accuracy with respect to a given benchmark or overall.

In Table 5 we present the mean squared errors (MSE), the Diebold and Mariano (DM) (1995) test of equal forecast accuracy and the Harvey et al. (HLN) (1998) test of forecast encompassing for the 15 best forecasting models of $u_t - u_{t-1}$, with forecast horizon from 1 to 3 months.¹⁰ For each forecast horizon the column labeled “Rank” gives the rank of each model in terms of lowest MSE. The first column labeled ‘n.’ denotes the number of the model. For the complete list of models see Table A.5 in the Appendix. We notice that for all forecast horizons the best model (i.e. the model with the lowest MSE out-of-sample) always includes the GI as the exogenous variable. In particular, the $ARX(1) - G_t$ (model #261), a standard AR(1) model with the average monthly GI, is the best model when forecasting both one and two months ahead. By the same token, the $ARMAX(1,1) - G_t - SA$ (model #398), a standard ARMA(1,1) model with the average monthly GI plus a multiplicative seasonal factor, has the best performance among the three-month-ahead forecasts. It is important to notice that, at all forecast horizons, the best fifteen models always include the GI as an independent variable, in some cases in combination with the IC. Anyway, at one step ahead, the best 3 models include the GI only as an exogenous variable (thus not including IC). The same is also true for the two-step-ahead horizon (the best 5 models include only GI) and, even more, at the three-step-ahead horizon where the best 11 models include only our preferred leading indicator. Table 5 also reports the best models estimated over the full and the short sample without the GI. The reader can notice that for 1-month-ahead forecasts the best model without the GI over the full sample ranks 73rd, while the same model over the short sample ranks 197th. For 2- and 3-month-ahead forecasts these models without the GI rank higher than 173rd.

¹⁰Additional estimates for u_t and $\log(u_t)$ can be found in tables A.7 and A.8 of the Appendix.

The literature on US unemployment forecasting has thus far only considered the ratios of the mean squared errors between a competitor model and a benchmark model to evaluate each model forecast ability. Nevertheless, after the seminal papers by Diebold and Mariano (1995) and West (1996), the community of forecasters has increasingly understood the importance of correctly testing for out-of-sample equal forecast accuracy. West (2006) provides a recent survey of the tests of equal forecast accuracy, while Busetti et al. (2009) provide extensive Monte Carlo evidence on the best tests of equal forecast accuracy or forecast encompassing to be used in any specific framework (nested or non-nested models). To provide a more formal assessment of the forecasting properties of each model in our horse-race, we use the best model in terms of lowest MSE as the benchmark model and perform two tests. The first is a two-sided DM test for the null of equal forecast accuracy between the benchmark and the competitor and a two-sided HLN test, to assess whether the benchmark model forecast encompasses the competitor.¹¹ Recall that a benchmark model forecast encompasses the k -th competitor model if the former cannot be significantly improved upon by a convex forecast combination of the two. In other words, the benchmark forecast encompasses the competitor if this latter model does not provide any additional information for predicting. We use the two-sided version of these tests because some models are nested and others are non-nested making the direction of the alternative hypothesis unknown. Using the two-sided version of the tests we can thus compare both nested and non-nested models, as is our case where the exogenous variable often differs from one model to another and only a subset of models are really nested. Furthermore, we use both the DM and the HLN because they can be compared to standard critical values of the Gaussian distribution and Busetti et al. (2009) show

¹¹The DM test is based on the loss differential between the benchmark (model 0) and the k -th competitor, i.e. $d_t = e_{0,t}^2 - e_{k,t}^2$. To test the null of equal forecast accuracy $H_0 : E(d_t) = 0$, we employ the DM statistic $DM = P^{1/2}\bar{d}/\hat{\sigma}_{DM}$, where \bar{d} is the average loss differential, P is the out-of-sample size, and $\hat{\sigma}_{DM}$ is the square-root of the long-run variance of d_t . The HLN test analyzes the null $H_0 : E(f_t) = 0$, where $f_t = e_{0,t}(e_{0,t} - e_{k,t})$. The HLN test statistic is $HLN = P^{1/2}\bar{f}/\hat{\sigma}_{HLN}$, where \bar{f} is the average of the forecast error differential multiplied by the forecast error of the benchmark model, P is the out-of-sample size and $\hat{\sigma}_{HLN}$ is the square root of the long-run variance of f_t . Both tests are distributed as a Gaussian under the null.

that the HLN test is rather powerful both in a nested and non-nested framework when compared to other more complicated tests with non-standard distributions.

From Table A.5 in the Appendix we can see that the best model in terms of the lowest MSE always beats the competitors estimated on the full sample in predicting the unemployment rate in first differences. According to the standard DM test we can reject the null of equal forecast accuracy at 10% for 1- and 2-month-ahead forecast horizons. The same happens with the HLN test. At 10% we reject the null at the forecast horizons of 1 and 2 months. This means that our best model outperforms all those models that use the whole time series of unemployment and IC for the longest available time span, even though the former is estimated over a very short time window (38 months). When the benchmark is compared to models estimated on the short sample, both the DM and the HLN tests reject the null of equal forecast accuracy at 1-month ahead. However, they fail to reject the null for forecast horizons longer than 1-month.

In order to formally test the out-of-sample forecasting performance of the models using our suggested new leading indicator, we apply White’s (2000) “Reality Check” (RC) test. This test builds on Diebold and Mariano (1995) and West (1996) and involves examining whether the expected value of the forecast loss (e.g. the squared forecast error in the case of MSE) of one or several models is significantly greater than the forecast loss of a benchmark model. We adopt this test because in contrast to the previous ones, it tests for superior predictive ability rather than only for equal predictive ability. Furthermore, the RC test also allows us to account for the dependence among forecasting models that can arise when several models using the same data are compared in terms of predictive ability. Failing to do so can result in data-snooping problems, which occur when one searches a model extensively until a good match with the given data is found. White (2000) develops a test of superior unconditional predictive ability among multiple models accounting for this specification search. With this test we compare all the competitor models together against a benchmark. The null hypothesis is that all the models are no better than the benchmark, i.e., $H_0 : \max_{1 \leq k \leq L} E(f_k) \leq 0$, where $f_k = e_{0,t}^2 - e_{k,t}^2$ for MSE losses. This is

a multiple hypothesis, the intersection of the one-sided individual hypotheses $E(f_k) \leq 0$, $k = 1, \dots, L$. The alternative is that H_0 is false, that is, there exists a model which is superior to the benchmark. If the null hypothesis is rejected, there must be at least one model for which $E(f_k)$ is positive.¹² Hansen (2005) shows that White’s Reality Check is conservative when a poor model is included in the set of L competing models. Hansen (2005) suggests using a studentized version of the RC test, suggesting the SPA test. We also tried the SPA test, but the two p-values are similar to the RC p-values and are not reported.

Table 6 reports the RC p-values for the best models against all the other models at each forecast horizon and for all the different transformations of the unemployment rate. In the Table we show the RC p-values for two different values of the probability parameter $q = (0.10, 0.50)$ and two different numbers of bootstrap replications $B = (2000, 5000)$. In boldface we report those RC p-values that are greater than the 5% significance level. We can notice that at this significance level we fail to reject the null hypothesis that none of the 519 competing models is better than our benchmark. Thus our best models with the GI have (almost always) superior predictive ability when compared to all the other models in our horse-race. However, we should acknowledge that these results must be interpreted with caution: we have a very short out-of-sample period and it is well known that the RC is undersized and has low power in small samples (see Hubrich and West, 2009).

¹²Suppose that $\sqrt{P}(\bar{f} - E(f)) \xrightarrow{d} N(0, \Omega)$ as $P(T) \rightarrow \infty$ when $T \rightarrow \infty$, for Ω positive semi-definite. White’s (2000) RC test statistic for H_0 is formed as $\bar{V} = \max_{1 \leq k \leq L} \sqrt{P} \bar{f}_k$, where $\bar{f}_k = P^{-1/2} \sum_{t=R+1}^T \hat{f}_{k,t}$. However, as the null limiting distribution of \bar{V} is unknown, White (2000) showed that the distribution of $\sqrt{P}(\bar{f}^* - \bar{f})$ converges to that of $\sqrt{P}(\bar{f} - E(f))$, where \bar{f}^* is obtained from the stationary bootstrap of Politis and Romano (1994). By the continuous mapping theorem this result extends to the maximal element of the vector $\sqrt{P}(\bar{f}^* - \bar{f})$, so that the empirical distribution of $\bar{V}^* = \max_{1 \leq k \leq L} \sqrt{P}(\bar{f}_k^* - \bar{f}_k)$ may be used to compute the p-value of the test. This p-value is called the ‘Reality Check p-value’.

5 Robustness checks

5.1 Nonlinear models

Most of the previous literature on unemployment forecasting in the US suggests using non-linear models to better approximate the long-term dynamic structure of its time series (see Montgomery et al., 1998 and Rothman, 1998). In particular, Montgomery et al. (1998) argue that Threshold Autoregressive (TAR) models can better approximate the unemployment rate dynamics especially during economic contractions, while linear ARMA models generally give a better representation of its short-term dynamics. To check the robustness of our best models which use the GI, we have also adopted some non-linear models that are typically used with the unemployment rate. We have estimated three non-linear time series models. The first is a self-exciting threshold autoregression (SETAR) model which takes the following form:

$$\begin{aligned} u_t = & [\phi_{01} + \phi_{11}u_{t-1} + \phi_{21}u_{t-2}] I(u_{t-1} \leq c) \\ & + [\phi_{02} + \phi_{12}u_{t-1} + \phi_{22}u_{t-2}] I(u_{t-1} > c) + \varepsilon_t \end{aligned} \quad (2)$$

where $I(\cdot)$ is the indicator function and c is the value of the threshold.

The SETAR models endogenously identify two different regimes given by the threshold variable u_{t-1} . In particular, following Rothman (1998) we adopted a SETAR model with two lags for each regime.

The second non-linear model used to forecast the unemployment rate is a logistic smooth transition autoregressive (LSTAR) model which is a generalization of the SETAR. The LSTAR model takes the form

$$\begin{aligned}
u_t &= [\phi_{01} + \phi_{11}u_{t-1} + \phi_{21}u_{t-2}] [1 - G(\gamma, c, u_{t-1})] \\
&+ [\phi_{02} + \phi_{12}u_{t-1} + \phi_{22}u_{t-2}] G(\gamma, c, u_{t-1}) + \varepsilon_t
\end{aligned} \tag{3}$$

where $G(\gamma, c, u_{t-1}) = [1 + \exp(-\gamma \prod_{k=1}^K (u_t - c_k))]^{-1}$ is the logistic transition function, $\gamma > 0$ is the slope parameter set to zero for identification and c is the location parameter. In this model the change from one regime to the other is much smoother than in the SETAR model.

The third non-linear model employed to predict the US unemployment rate is an additive autoregressive model (AAR) of the following form

$$u_t = \mu + \sum_{i=1}^m s_i(u_{t-(i-1)d}) \tag{4}$$

where s_i are smooth functions represented by penalized cubic regression splines. The AAR model is a generalized additive model that combines additive models and generalized linear models. These models maximize the quality of prediction of a target variable from various distributions, by estimating a non-parametric function of the predictor variables which are connected to the dependent variable via a link function (see Hastie and Tibshirani, 1990). We have included this additional model to enlarge our out-of-sample comparison to non-parametric models which are found superior in predicting the US unemployment by Golan and Perloff (2004).

Panel C of Table 5 reports the MSE, the DM test and the HLN test for 1- to 3-month-ahead forecasts from these three non-linear models estimated only up to the second lag for the first differences of the US unemployment rate. At 1-month ahead the best non-linear model is the SETAR which ranks 258th, then the AAR (276) and the LSTAR (362). Thus, as previously found in the literature, non-linear models do not seem to be suitable for short-term forecasting. These non-linear models tend to fare better as soon as we forecast the unemployment rate at two and, in particular, at three months ahead, where their

rank ranges between the 24th and the 35th. We can thus conclude that our simple linear model using our preferred leading indicator (GI) also outperforms non-linear models, even though the gain tends to shrink as the forecast horizon increases.¹³

5.2 State level forecasts

As a further robustness check for the predictive properties of the GI, we estimated the same 520 models for each of the 51 states (including the District of Columbia), assessing the percentage of states for which the best model in terms of lower MSE is the one using the GI.

For the first-differenced series ($u_t - u_{t-1}$), the baseline in our forecast comparison, the percentage of the best models adopting the GI as a leading indicator ranges from 75% to 84% for the 1-step-ahead and the 3-step-ahead, respectively. When we use US unemployment rate in levels (u_t) as the dependent variable, the percentage of GI models with the lowest MSE out-of-sample ranges between 69% for the 2-step-ahead forecasts and 82% for the 3-step-ahead.

Finally, we test whether the aggregation of the 51 state models could improve the forecasting performance over the federal level benchmark. In particular, for each state we select the model with the lowest MSE and then aggregate the single state best forecasts using different weights. In Table 7 we compare the out-of-sample results of this aggregation with the benchmark model estimated at the federal (US) level, reported in the first row of each sub-panel as ‘best’ model. This model is characterized by the lowest MSE for the unemployment rate in first differences and in levels.

In particular, in the second row of Panel A of Table 7 we report the federal level forecasts obtained aggregating the state level estimates without weighting (simple average). In the third row, we weight the state level forecasts using the share of the labor force

¹³When we forecast the level u_t or the log-level $\log(u_t)$ of unemployment (see Tables A.7 and A.8 in the Appendix), these results hold only partially. In fact, non-linear models tend to rank poorly even at longer forecast horizon, thus showing that the linear models with Google clearly outperform nonlinear models even at longer horizons.

(employed plus unemployed) in state i on the total federal labor force. In the fourth row, this share is further weighted by the state i diffusion of the internet (See Table A.6 of the Appendix for descriptive statistics on internet diffusion among the entire population, among the active population aged 15-64, and among the 15-64 unemployed). The last row of each sub-panel is weighted by the share of unemployed combined with the 15-64 share of unemployed using internet. We define as internet diffusion in state i the share of individuals (active 15-64 individuals or unemployed 15-64 individuals according to the definition used) living in a household where at least an individual uses the internet.¹⁴

Forecasts obtained aggregating estimates of single state forecasts are inferior to the federal ones at all forecast horizons. Nevertheless, it is interesting to note that the gap between the best federal model and the aggregation of the 51 state models reduces as the forecast horizon increases, with MSEs being very close to the best federal-level forecasts in the three-step-ahead predictions. A more in-depth investigation of these patterns could be an interesting starting point for further research, but is beyond the scope of the present article.

5.3 Comparison with the Survey of Professional Forecasters

As an additional robustness check we compare the forecasts of our best model with the results of the Survey of Professional Forecasters (SPF), a quarterly survey of about 30 professionals, conducted by the Federal Reserve Bank of Philadelphia.¹⁵ The survey publishes estimates of the quarterly evolution of a set of macroeconomic variables approximately in the middle of the quarter.¹⁶

In Figure 5, we compare simple forecast errors for the median (SPF^{median}), the mean (SPF^{mean}) and the best individual forecast¹⁷ (SPF^{best}) of the SPF with those relative

¹⁴We calculate the weights using the results of the October 2007 supplement of the Current Population Survey (CPS). The exact question used for calculating the weights asks: *Do you (Does anyone) in this household use the Internet at any location? The possible answers are simply Yes/No.*

¹⁵<http://www.phil.frb.org/research-and-data/real-time-center/survey-of-professional-forecasters/>.

¹⁶The SPF is issued around the 15th of February, May, August and November.

¹⁷The best individual forecast is calculated ex-post once the real values for $u_t - u_{t-1}$ are known.

to the forecasts for each quarter obtained from a group of six best models. We define these best models as i) our best model overall (the one using the *GI*); ii) the best model among those not using the *GI* (*IC*) over the full sample; and iii) the best model among those not using the *GI* over the short sample (*IC_s*). To these three groups of best models we add three additional groups of non-linear models based on iv) the SETAR(2), v) the LSTAR(2) and vi) the AAR(2) model.

From each group we compute three series of quarterly forecasts. 1) $x^{1st-month}$ are the 1-month-ahead forecasts computed in the last month of each quarter before the one we want to forecast.¹⁸ The prediction for the whole quarter is equal to the forecast for the first month of the quarter. 2) $x^{2nd-month}$ are the 2-month-ahead forecasts computed in the last month of the quarter before, with the estimate for the whole quarter being equal to the estimate for the second, central, month. Both these forecasts are very conservative with respect to those of SPF, since the SPF is issued on the 15th of the second month of each reference quarter, thus around 45 days after our estimates are produced. Finally, 3) x^{Comb} are the quarterly forecasts computed as the average of the realized unemployment rate for the first month and the 1- and 2-month-ahead forecasts generated at the end of the first month of the reference quarter. These latter forecasts are less conservative because they use all the information available when the SPF is released. We thus expect that such forecasts should be at least as accurate as the SPF.

Does our model with Google outperform the professionals? It does, by a considerable margin, if we consider that it only uses a very short sample. In Table 8 we report the MSE for the nine best models and the three SPF forecasts over the period 2007Q2-2009Q2 along with the DM and the HLN tests where the benchmark is the model G^{Comb} , that is the model with the lowest MSE (in boldface). It is evident that the model including the *GI* outperforms all the three SPF forecasts, having a MSE lower by an order of magnitude. The DM test shows that the benchmark model is significantly better than all the other competitors using the first and second month forecasts, except for the less

¹⁸For example, if we want to forecast the quarterly unemployment rate for 2008Q2, at 2008.3 we compute the 1-month-ahead forecast from one of our three best models.

conservative forecasts x^{Comb} for which we reject the null hypothesis of equal forecast accuracy. Instead, the HLN test rejects the null that the benchmark model forecast encompasses the competitors, except for IC_s^{Comb} and $IC^{2nd-month}$. Figure 5 depicts the forecast errors from the best six models (those with the lowest MSE in Table 8) in addition to the mean and median SPF forecasts. It is rather clear that the model including the GI has the best performance in most periods, and in particular when the current recession worsened after the Lehman collapse in 2008Q4. We can see that the SPF and all the non-linear time series models tend to under-predict, whereas the linear models using either the IC or the GI tend to over-predict. While the models including the GI tend to give forecast errors that are close to zero, both the mean and median of the SPF tend to under-predict the real unemployment rate. This means that our simple linear ARMA models with the GI as a leading indicator outperform the predictions of the professional forecasters also during contractions, when the social impact of a high unemployment rate is even greater and the loss attached to high and positive forecast errors is maximal.¹⁹

6 Conclusions

Following the growing popularity of the internet as a job search tool and the increasing need of reliable and updated unemployment forecasts, especially during periods of economic downturn, in this paper we suggest the use of the Google index (GI), based on internet job-search performed through Google, as the best leading indicator to predict the US unemployment rate.

Popular time series specifications augmented with this indicator definitely improve their out-of-sample forecasting performance both at one-, two- and three-month horizons. Our results from the out-of-sample horse-race with more than five hundred linear and non-linear specifications show that the best models in terms of lowest MSE are always

¹⁹We have also performed the same robustness check for the forecasts using the level of the unemployment rate finding even more striking results that are unreported. In this case, all the model using GI outperform the SPF and, in particular, the best model is the $GI^{2-month}$.

those using the GI as the leading indicator. These models fare better also in comparison to other similar models estimated on a longer (or on the same) time span and using the initial claims (IC) as a leading indicator. These models outperform all the others both in terms of equal forecast accuracy and in terms of superior predictive ability. Our results are robust to various transformations of the dependent variable and are confirmed when assessing the predictive power of the GI in state-level forecasting. The best model including the GI also outperforms the forecasts released in the Survey of Professional Forecasters conducted by the Philadelphia Fed.

Notwithstanding its limited time availability (Google data start in January 2004) we believe that the GI should routinely be included in time series models to predict unemployment dynamics. It is easy to guess that the use of internet-based data will become widespread in economic research in the near future.

Notes: u_t is the US unemployment rate in levels, $u_t - u_{t-1}$ are the first differences, $\log(u_t)$ is the unemployment rate in logs, $u_t^{logit} = \log(u_t/(1-u_t))$ is the logistic transformation suggested by Koop and Potter (1999), u_t^{LLD} is the log-linear de-trended unemployment rate and u_t^{LHP} is the HP-filtered series in log, both suggested by Rothman (1998). IC and G are the monthly initial claims and the monthly Google job search index used as leading indicators. The subscripts wj indicate the j^{th} week and $t-k$, $k = (0, 1, 2)$ is the time lag. ***, ** and * indicate rejection at 1, 5 and 10%, respectively.

Notes: u_t is the US unemployment rate in levels, $u_t - u_{t-1}$ are the first differences, $\log(u_t)$ is the unemployment rate in logs, $u_t^{logit} = \log(u_t/(1 - u_t))$ is the logistic transformation suggested by Koop and Potter (1999), u_t^{LLD} is the log-linear de-trended unemployment rate and u_t^{LHP} is the HP-filtered series in log, both suggested by Rothman (1998). IC and G are the monthly initial claims and the monthly Google job web search index used as leading indicators. Both the subscripts and superscripts wj indicate the j^{th} week and the subscripts $t - k$, $k = (0, 1, 2)$ is the time lag. ***, ** and * indicate rejection at 1, 5 and 10%, respectively.

	$DF - GLS^\tau$	-4.414***		$DF - GLS^\tau$	-2.523
u_t^{LLD}	$DF - GLS^\mu$	-1.344	u_t^{LLD}	$DF - GLS^\mu$	-2.823***
	$DF - GLS^\tau$	-2.190		$DF - GLS^\tau$	-2.797

Notes: The $DF - GLS^\mu$ test indicates the test where a constant is included as the exogenous regressor, while $DF - GLS^\tau$ is the test with a constant and trend included. The critical values at 1, 5, and 10% for the $DF - GLS^\mu$ test are -2.569 (-2.600), -1.941 (-1.946) and -1.616 (-1.614), respectively, for the full sample 1967.1-2009.6 (short sample 2004.1-2009.6). Instead, the critical values at 1, 5, and 10% for the $DF - GLS^\tau$ test are -3.48 (-3.709), -2.89 (-3.138) and -2.57 (-2.842), respectively, for the full sample 1967.1-2009.6 (short sample 2004.1-2009.6). ***, ** and * indicate rejection at 1, 5 and 10%, respectively.

Table 4: Forecasting Models: $\phi(L)y_t = \mu + x_t'\beta + \theta(L)\varepsilon_t$ for the unemployment rate

Notes: The null hypothesis of the Reality Check test is that none of the models beat the benchmark (i.e. our best model with Google index with the lowest MSE overall). B indicates the number of bootstrap replications and q is the probability parameter of the stationary bootstrap implemented to compute the Reality Check p -values. In boldface we indicate all the Reality Check p -values significant at 5% or more.

Notes: ***, ** and * indicate rejection at 1, 5 and 10%, respectively. The best federal level model is the model ranked first in the horse-race of table 5. Aggregation of state level models is made by taking the model with the lowest MSE for each state and then aggregating in a federal level forecast using a simple or weighed average as described in the table. Rk1 is the rank of each model within the table, while Rk2 is the rank of the model among all the models.

Notes: In this table we compare the SPF one-quarter-ahead unemployment forecasts with similar forecasts generated from our best models for $u_t - u_{t-1}$, i.e. models n. 261, 261 and 398 for 1-, 2- and 3-month-ahead forecasts, respectively. The out-of-sample period is 2007.2-2009.6. *SPF^{best}* is the best individual forecaster in the survey, *SPF^{mean}* is the mean of the forecasts, while *SPF^{median}* is the median. Models *x^{1st-month}* are 1-month-ahead forecasts computed in the last month of the quarter before. Models *x^{2nd-month}* are 2-month-ahead forecasts computed in the last month of the quarter before. Both these forecasts are very conservative since the SPF is issued on the 15th of the second month of each reference quarter. Models *x^{Comb}* compute the quarterly forecast as the average of the realized unemployment rate for the first month and the 1- and 2-month-ahead forecasts generated at the end of the first month of the reference quarter. The model with Google is the best model overall, the model with *IC* is the best model without Google, while the models with subscript *IC_s* is the best model without Google in the short sample. SETAR, LSTAR and AAR are the corresponding non-linear models estimated over the full sample up to the second lag. In boldface we indicate the model with the minimum MSE, while in italics the next to the minimum MSE. The benchmark model for the DM and HLN tests is *G^{Comb}*. ***, ** and * indicate rejection at 1, 5 and 10%, respectively.

Figure 1: Relative incidence of keyword searches through Google

Notes: The figure depicts the relative incidence of the keyword searches 'jobs', 'facebook', 'job offer', and 'youtube' over the relevant sample 2004.1-2009.6.

Figure 2: Exact timing of monthly US Unemployment rate calculation

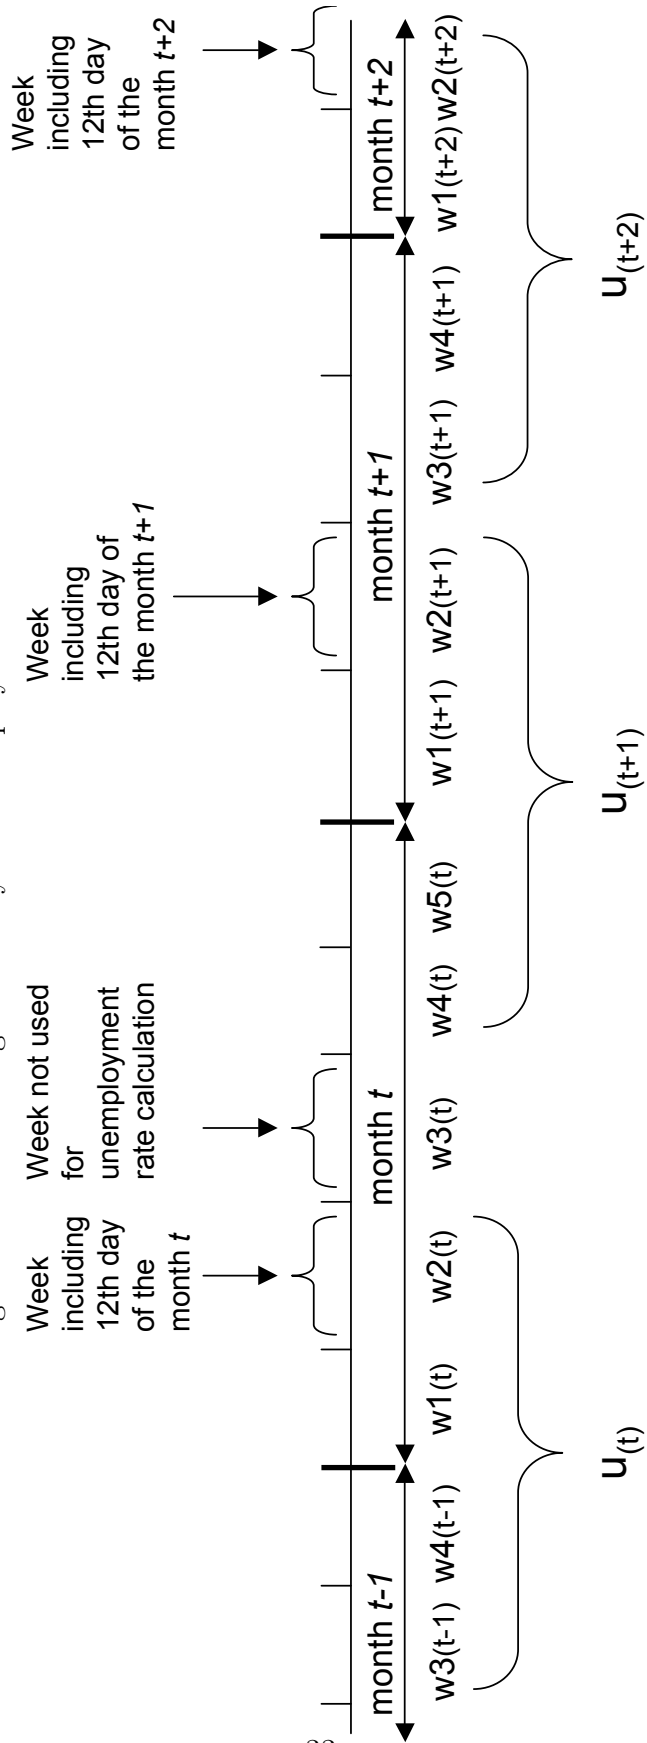

Figure 3: US Unemployment rate and Initial claims: Sample 1967:1-2009:6

Notes: Shaded areas identify official NBER recessions.

Figure 4: US Unemployment rate, Initial claims and Google index: Sample 2004:1-2009:6

Notes: Shaded areas identify NBER recessions. The Initial claims are monthly averages rebased on their maximum over the sample 2004:1-2009:6. The Google index is the monthly average of Google 'job' searches rebased on their maximum value over the sample 2004:1-2009:6.

Figure 5: Forecast errors from quarterly forecasts of the US unemployment rate: comparison of the best models with the Survey of Professional Forecasters

Notes: In this table we compare the SPF one-quarter-ahead unemployment forecasts with similar forecasts generated from our best models for $u_t - u_{t-1}$, i.e. models n. 261, 261 and 398 for 1-, 2- and 3-month-ahead forecasts, respectively. The out-of-sample period is 2007.2-2009.6. SPF^{best} is the best individual forecaster in the survey, SPF^{mean} is the mean of the forecasts, while SPF^{median} is the median. Models $x^{1st-month}$ are 1-month-ahead forecasts computed in the last month of the quarter before. Models $x^{2nd-month}$ are 2-month-ahead forecasts computed in the last month of the quarter before. Both these forecasts are very conservative because the SPF is issued on the 15th of the second month of each reference quarter. Models x^{Comb} compute the quarterly forecast as the average of the realized unemployment rate for the first month and the 1- and 2-month-ahead forecasts generated at the end of the first month of the reference quarter. The model with Google (G) is the best model overall, the model with the Initial Claims (IC) is the best model without Google, while the models with subscript IC_s is the best model without Google in the short sample. SETAR, LSTAR and AAR are the corresponding non-linear models estimated over the full sample up to the second lag.

A Not-for-publication Appendix: Further Tables and Figures

Notes: Authors calculations using the October 2007 CPS computer use supplement. State internet diffusion is expressed in relative terms with the the federal average normalized to one. The actual diffusion at the national level is equal to 76.2, 82.6 and 76.5 respectively for total, active and unemployed population.

Table A.7: Forecasting US unemployment rate (u_t) in levels. Best 15 models in terms of lowest MSE, best models without GI and non-linear models.

Notes: ***, ** and * indicate rejection at 1, 5 and 10%, respectively. This table reports the best 15 models in terms of MSE among the 523 estimated ones. The complete list of models and their forecasting performance is available in the Appendix (table A.5). SA indicates the model augmented with a multiplicative seasonal factor.

Table A.8: Forecasting US unemployment rate in logs ($\log(u_t)$). Best 15 models, best models without GI and non-linear models.
