A case of neuromyelitis optica (Devic's disease)

SGP Kumuduni¹, Athula Dissanayaka²
¹Registrar in Medicine, ²Consultant Neurologist, Teaching Hospital, Karapitiya, Galle.

Introduction

Neuromyelitis optica is an inflammatory disease of the central nervous system in which there are episodes of inflammation and damage to the myelin that almost exclusively affect the optic nerves and spinal cord. It usually causes temporary blindness, occasionally permanent, in one or both eyes. It can also lead to varying degrees of weakness or paralysis in the legs or arms, loss of sensation, and/or bladder and bowel dysfunction from spinal cord damage.

Case report

A 40 year old previously healthy man was admitted with sudden onset urine retention and weakness of lower limbs extending to upper limbs, associated with sudden loss of vision in both eyes, one week following a febrile illness.

Examination revealed flaccid paraparesis of both lower limbs with a sensory level at thoracic10 for all sensory modalities. Reflexes were absent in the lower limbs. There was grade 3 weakness of upper limbs. Bladder and bowel functions
were also affected. Visual acuity was 6/12 in the right eye and 1/60 in the left eye. Both optic discs were pale with bilateral relatively apparent papillary defect.

His CSF was normal. MRI scan of the thoracic spine and brain revealed demyelination. With the clinical and investigation findings the diagnosis of a rare disease neuromyelitis optica was made and treatment started with high dose steroids (methylprednisolone 500mg daily for 5 days) and plasma exchange. Unfortunately patient did not recover fully although his upper limb weakness has improved.

**Discussion**

Neuromyelitis optica often follows a sore throat, common cold or other febrile illness. Either the ocular or the spinal lesion may develop first, separated by days or weeks or both may occur simultaneously. The ocular lesion may be an optic neuritis or a retro bulbar neuritis. The spinal cord lesion which may be heralded by severe pain in the back and limbs lead to usual features of transverse myelitis with paralysis of upper motor neurone type and loss of sensation below the level of the lesion and of sphincter control.

There are two major types of neuromyelitis optica. In the first type, optic neuritis and myelitis episodes tend to come very close together often within days or weeks and there is no recurrence after the initial flurry of symptoms. In the second form, repeated episodes of optic neuritis and myelitis that are separated by months or years occur. The combination of neurological impairments which occur in patients with neuromyelitis optica can also be seen in multiple sclerosis (MS), acute disseminated encephalomyelitis (ADEM), systemic lupus erythematosus (SLE) and Sjögren syndrome.

CSF may show no abnormality or there may be an increase of protein and globulin, an excess of cells, usually mononuclear though occasionally neutrophils, have been described. There is usually an increase in oligoclonal immunoglobulins. Longitudinally extensive transverse myelitis (LETM) is the usual spinal cord finding in the MRI of the neuromyelitis optica. The MRI findings of neuromyelitis optica can to some degree overlap with MS but in general MS has discrete lesions. The MRI of the brain would be initially normal. But later on it may reveal MS like white matter lesions. The morphology and distribution of these lesions tend to differ from that in MS. The defining hallmark of this disease at this time is the identification in the patient's serum of a particular antibody, the NMO - IgG antibody that appears against a particular protein - an aqua protein - that is located in areas that are affected in neuromyelitis optica. It is a reliable biomarker to distinguish neuromyelitis optica from MS. This antibody seems to be present in about 70 percent of patients with neuromyelitis optica and is not found in people with MS or other similar conditions.

There is no cure for neuromyelitis optica, but there are therapies to reduce symptoms, and to prevent relapses. Usually the initial attack of neuromyelitis optica is treated with a combination of a corticosteroid drug (methylprednisolone) to stop the attack, and an immunosuppressive drug (azathioprine) for prevention of subsequent attacks. If frequent relapses occur, some individuals may need to continue a low dose of steroids for longer periods. Plasma exchange is used for people who are unresponsive to corticosteroid therapy. Pain, stiffness, muscle spasms, and bladder/bowel control problems can be managed with the appropriate medications and therapies. Individuals with major disability will require the combined efforts of occupational therapists, physiotherapists and social services professionals to address their complex rehabilitation needs.

A case of Castleman disease with pulmonary hypertension

WT Pradeep Gunasekara¹, SK Kodisinghe²
¹Registrar in Medicine, ²Senior House Officer in Oncosurgery, Teaching Hospital, Karapitiya, Galle.

Introduction
Castleman disease, also known as Giant lymph node hyperplasia or Angiofollicular lymph node hyperplasia, is a disease of lymph nodes and related tissues. It is not considered as a malignancy but one variety of it acts like lymphoma.

Case report
A 52 year old male was admitted to Teaching Hospital Karapitiya with loss of weight for 1 year, abdominal distension for 6 months and loss of appetite for 1 month. There was no history of fever. He had stable angina and was on anti-anginals, aspirin and verapamil.

On examination he was emaciated, pale and had large, discrete, firm and non-tender lymphadenopathy in the cervical, axillary and inguinal regions. Clinically he had cardiomegaly, a grade 4 pansystolic murmur best heard in the lower sternum and radiating to the axilla and a loud pulmonary second heart sound. Respiratory system was normal except for few bilateral fine basal crepitations. Abdominal examination showed a 5 cm hepatomegaly and splenomegaly.

His haemoglobin was 9.9 g/dL while white cell and platelet counts were normal. Blood picture showed hypochromic red cells while bone marrow examination showed normal active marrow. ESR was elevated at 80 mm/1st hour. Liver enzymes were normal and Mantoux test was negative. Ultrasound scan of the abdomen showed hepatomegaly with normal echo texture and no focal lesions and splenomegaly. There was no intra-abdominal lymphadenopathy or ascites. ECG showed right axis deviation and evidence of right atrial enlargement. Chest radiograph showed gross cardiomegaly and oligaeemic lung fields. 2D Echo found severe tricuspid regurgitation and dilated right ventricle and atrium indicative of severe pulmonary hypertension. There was also a small pericardial effusion. Lung function tests were compatible with restrictive lung disease. Biopsy from an axillary lymph node showed features suggestive of Castleman disease. HIV antibody was negative.

Discussion
Castleman disease usually presents with fever, weight loss, fatigue, night sweats, infections and anaemia. Pulmonary hypertension has been rarely reported in association with multicentric Castleman disease. Only three such reported cases were found during the literature search. Of these, two had tested negative for HIV while the other had tested positive. The proposed mechanism for pulmonary hypertension has been promotion of angiogenesis by Interleukin-6 produced in the germinal centres of hyperplastic lymph nodes.

Castleman disease may present in a localized form or a multicentric form. The localized form only affects a single lymph node group, most often in the chest and abdomen. The multicentric form affects more than one group of lymph nodes and also other organs containing
