A Simple CLNP-based Proposal for Internet Addressing and Routing

1 Summary

The Internet is approaching a situation in which the current IP address space is no longer adequate for global addressing and routing. This is causing problems including: (i) Internet backbones and regionals are suffering from the need to maintain large amounts of routing information which is growing rapidly in size (approximately doubling each year); (ii) The Internet is running out of IP network numbers to assign. There is an urgent need to develop and deploy an approach to addressing and routing which solves these problems and allows scaling to several orders of magnitude larger than the existing Internet. However, it is necessary for any change to be deployed in an incremental manner, allowing graceful transition from the current Internet without disruption of service. [1]

This paper describes a "Simple, CLNP-based Proposal" (SCP), which provides a long-term solution to Internet addressing, routing, and scaling. This involves a gradual migration from the current Internet Suite (based on Internet applications, running over TCP or UDP, running over IP) to an updated suite (based on the same Internet applications, running over TCP or UDP, running over CLNP [2]). This paper describes a proposal for how transition may be accomplished. Description of the manner in which use of CLNP, NSAP addresses, and related protocols (ES-IS, IS-IS, and IDRP) allow scaling to a worldwide Internet is outside of the scope of this paper.

Originally, it was thought that any practical proposal needed to address the immediate short-term problem of routing information explosion (in addition to the long-term problem of scaling to a worldwide Internet). This could require older IP-based systems to talk to other older IP-based systems over intervening Internet backbones which did not support IP. This in turn could require either translation of IP packets into CLNP packets and vice versa, or encapsulation of IP packets inside CLNP packets. However, other shorter-term techniques [3] have been proposed which will allow the Internet to operate successfully for several years using the current IP address space. This in turn allows more time for IP-to-CLNP migration, which in turn allows for a much simpler migration technique.

The SCP proposal therefore makes use of a simple long-term migration proposal based on a gradual update of DNS servers (to return larger addresses) and Internet Hosts (to run Internet applications over CLNP). This proposal requires routers to be updated to support forwarding of CLNP (in addition to IP). However, this proposal does not require encapsulation nor translation of packets nor address mapping. IP addresses and NSAP addresses may be assigned and used independently during the migration period. Routing and forwarding of IP and CLNP packets may be done independently.

This is a draft paper. Some details of the operation of SCP have been left for further study.

2 Long-Term Goal of SCP

This proposal seeks to take advantage of the success of the Internet Suite, the greatest part of which is probably the use of IP itself. IP offers a ubiquitous network service, based on datagram

(connectionless) operation, and on globally significant IP addresses which are structured to aid routing. Unfortunately, the limited 32-bit IP address is gradually becoming inadequate for routing and addressing in a global Internet. Scaling to a worldwide Internet requires much larger addresses allowing a multi-level hierarchical address assignment.

If we had the luxury of starting over from scratch, most likely we would base the Internet on a new datagram internet protocol with much larger multi-level addresses. In principle, there are many choices available for a new datagram internet protocol. For example, the current IP could be augmented by addition of larger addresses, or a new protocol could be developed. However, the development, standardization, implementation, testing, debugging and deployment of a new protocol (as well as associated routing and host-to-router protocols) would take a very large amount of time and energy, and is not guaranteed to lead to success. In addition, there is already such a protocol available. In particular, the ConnectionLess Network Protocol (CLNP [1]) is very similar to IP[1], and offers the required datagram service and address flexibility. CLNP is currently being deployed in the Internet backbones and regionals, and is available in vendor products. This proposal does not actually require use of CLNP (the main content of this proposal is a graceful migration path from the current IP to a new IP offering a larger address space), but use of CLNP will be assumed.

This proposal seeks to minimize the risk associated with migration to a new IP address space. In addition, this proposal is motivated by the requirement to allow the Internet to scale, which implies use of Internet applications in a worldwide Internet. It is therefore proposed that existing Internet transport and application protocols continue to operate unchanged, except for the replacement of 32-bit IP addresses with larger addresses. The use of larger addresses will have some effect on applications, particularly on the Domain Name Service. SCP proposal would not mean having to move over to OSI completely. It would mean only replacing IP with CLNP. TCP, UDP, and the traditional TCP/IP applications would run on top of CLNP.

The long term goal of the SCP proposal involves transition to a worldwide Internet which operates much as the current Internet, but with CLNP replacing IP and with NSAP addresses replacing IP addresses. Operation of this updated protocol suite will be very similar to the current operation. For example, in order to initiate communication with another host, a host will (in most cases) contact the DNS server, obtain a mapping from the known DNS name to a network (internet) address, and send application packets encapsulated in TCP or UDP, which are in turn encapsulated in CLNP. This long term goal requires a specification for how TCP and UDP are run over CLNP. Similarly, DNS servers need to be updated to deal with NSAP addresses, and routers need to be updated to forward CLNP packets. This proposal does not involve any wider-spread migration to OSI protocols.

3 Migration

Figure 1 illustrates the basic operation of SCP. Illustrated is a single Internet Routing Domain, which is also interconnected with Internet backbones and/or regionals. Illustrated are two "updated" Internet Hosts N1 and N2, as well as two older hosts H1 and H2, plus a DNS server and two border routers. It is assumed that the routers internal to the routing domain are capable of forwarding both IP and CLNP traffic (this could be done either by using multi-protocol routers which can forward both protocol suites, or by using a different set of routers for each suite).

[1]The initial development of CLNP was based on an international standardization of IP, but with provision for larger multi-level addresses with a flexible address structure.

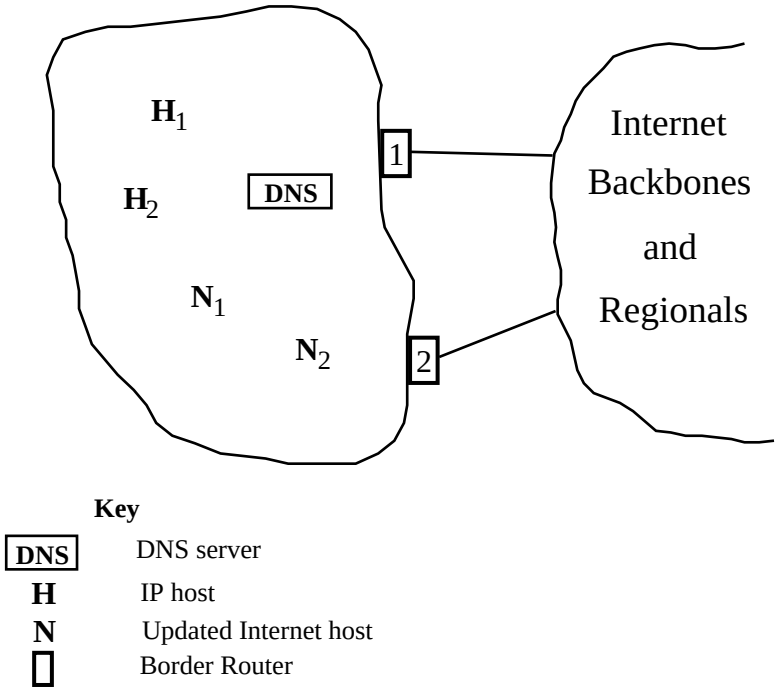

Figure 1 - Overview of SCP

Updated Internet hosts talk to old Internet hosts using the current Internet suite unchanged. Updated Internet hosts talk to other updated Internet hosts using (TCP or UDP over) CLNP. This implies that updated Internet hosts must be able to send either old-style packets (using IP), or new style packet (using CLNP). Which to send is determined via the normal DNS name-to-address lookup.

Thus, suppose that host N1 wants to communicate with host H1. In this case, N1 contacts the DNS server by sending a normal DNS request to its local DNS server. In this case, since H1 is a older (not-updated) host, the address available for H1 is an IP address, and thus the DNS response returned to N1 specifies an IP address. This allows N1 to know that it needs to send a normal old-style Internet Suite packet (encapsulated in IP) to H1.

Suppose that host N1 wants to communicate with host N2. In this case, again N1 contacts the DNS server by sending a DNS request to the DNS server. If either the DNS server or the routers in the domain have not been updated (to handle NSAP addresses and CLNP respectively) then the DNS server will again respond with a normal IP address, and the communication between N1 and N2 will use IP. However, assuming that the DNS server has been updated (to be able to return NSAP addresses), that the routers in the domain have been updated (to forward CLNP), and that the appropriate resource records for NSAP addresses have been configured into the DNS server, then the DNS server will respond to N1 with the NSAP address for N2, allowing N1 to know to use CLNP (instead of IP) for communication with N2.

A new resource record type will be defined for NSAP addresses. New hosts ask for both the new and old (IP address) resource records. Older DNS servers will not have the new resource record type, and will therefore respond with only IP address information. Updated DNS servers will have the new resource record information for the requested DNS name only if the associated host has been updated (otherwise the updated DNS server again will respond with an IP address).

4 Running TCP and UDP Over CLNP

TCP is run directly on top of CLNP (i.e., the TCP packet is encapsulated directly inside a CLNP packet -- the TCP header occurs directly following the CLNP header). Use of TCP over CLNP is straightforward, with the only non-trivial issue being how to generate the TCP pseudo-header (for use in generating the TCP checksum).

Note that the SCP proposal runs TCP over CLNP on an end-to-end basis (for example, there is no intention to translate CLNP packets into IP packets). This implies that only "consenting updated systems" will be running TCP over CLNP, which in turn implies that backward compatibility with existing systems is not an issue. There are therefore several options available for how to generate the pseudoheader. The pseudoheader could be set to all zeros (implying that the TCP header checksum would only be covering the TCP header). Alternatively, the pseudoheader could be calculated from the CLNP header. For example, the "source address" in the TCP pseudoheader could be replaced with two bytes of zero plus a two byte checksum run on the source NSAP address length and address (and similarly for the destination address); the "protocol" could be replaced by the destination address selector value; and the "TCP Length" could be calculated from the CLNP packet in the same manner that it is currently calculated from the IP packet. The details of how the pseudoheader is composed is for further study.

UDP is transmitted over CLNP in the same manner. In particular, the UDP packet is encapsulated directly inside a CLNP packet. Similarly, the same options are available for the UDP pseudoheader as for the TCP pseudoheader.

5 Updates to the Domain Name Service

SCP requires that a new DNS resource record entry type ("long-address") be defined, to store longer internet (i.e., NSAP) addresses. This resource record allows mapping from DNS names to NSAP addresses, and will contain entries for systems which are able to run Internet applications, over TCP or UDP, over CLNP.

The presence of a "long-address" resource record for mapping a particular DNS name to a particular NSAP address can be used to imply that the associated system is an updated Internet host. This specifically does **not** imply that the system is capable of running OSI protocols for any other purpose. Also, the NSAP address used for running Internet applications (over TCP or UDP over CLNP) does not need to have any relationship with other NSAP addresses which may be assigned to the same host. For example, a "dual stack" host may be able to run Internet applications over TCP over CLNP, and may also be able to run OSI applications over TP4 over CLNP. Such a host may have a single NSAP address assigned (which is used for both purposes), or may have separate NSAP addresses assigned for the two protocol stacks. The "long-address" resource record, if present, may be assumed to contain the correct NSAP address for running Internet applications over CLNP, but may not be assumed to contain the correct NSAP address for any other purpose.

The backward translation (from NSAP address to DNS name) is facilitated by definition of an associated resource record. This resource record is known as "long-in-addr.arpa", and is used in a manner analogous to the existing "in-addr.arpa".

Updated Internet hosts, when initiating communication with another host, need to know whether that host has been updated. The host will request the address-class "internet address", entry-type

"long-address" from its local DNS server. If the local DNS server has not yet been updated, then the long address resource record will not be available, and an error reponse will be returned. In this case, the updated hosts must then ask for the regular Internet address. This allows updated hosts to be deployed in environments in which the DNS servers have not yet been updated.

An updated DNS server, if asked for the long-address corresponding to a particular DNS name, does a normal DNS search to obtain the information. If the long-address corresponding to that name is not available, then the updated DNS server will return the resource record type containing the normal 32-bit IP address (if available). This allows more efficient operation between updated hosts and old hosts in an environment in which the DNS servers have been updated.

Interactions between DNS servers can be done over either IP or CLNP, in a manner analoguous to interactions between hosts. DNS servers currently maintain entries in their databases which allow them to find IP addresses of other DNS servers. These can be updated to include a combination of IP addresses and NSAP addresses of other servers. If an NSAP address is available, then the communication with the other DNS server can use CLNP, otherwise the interaction between DNS servers uses IP. Initially, it is likely that all communication between DNS servers will use IP (as at present). During the migration process, the DNS servers can be updated to communicate with each other using CLNP.

6 Other Technical Details

When 32-Bit IP addresses Fail

Eventually, the IP address space will become inadequate for global routing and addressing. At this point, the remaining older (not yet updated) IP hosts will not be able to interoperate directly over the global Internet. This time can be postponed by careful allocation of IP addresses and use of "Classless Inter-Domain Routing" (CIDR [3]), and if necessary by encapsulation (either of IP in IP, or IP in CLNP) [reference]. In addition, the number of hosts affected by this can be minimized by aggressive deployment of updated software based on SCP.

When the IP address space becomes inadequate for global routing and addressing, for purposes of IP addressing the Internet will need to be split into "IP address domains". 32-bit IP addresses will be meaningful only within an address domain, allowing the old IP hosts to continue to be used locally. For communications between domains, there are two possibilities: (i) The user at an old system can use application layer relays (such as mail relays for 822 mail, or by Telnetting to an updated system in order to allow Telnet or FTP to a remote system in another domain); or (ii) Network Address Translation can be used [4].

Hosts which do not use DNS

For hosts and applications that do not use DNS, there are three options available: (i) Update the host and the application to use DNS; (ii) Update the alternate means (such as host tables) that are used for name to address lookup to be able to return NSAP addresses; (iii) Continue to use the host and application running over IP; when the IP addresses become no longer globally unique then the host becomes limited to local use (within the local IP addressing domain).

Applications which use IP Addresses Internally

There are some application protocols (such as FTP and NFS) which pass around and use IP addresses internally. Migration to a larger address space (whether based on CLNP or other protocol)

will require either that these applications be limited to local use (within an "IP address domain" in which 32-bit IP addresses are meaningful) or be updated to either: (i) Use larger network addresses instead of 32-bit IP addresses; or (ii) Use some other globally-significant identifiers, such as DNS names.

Local Network Address Translation

Network Address Translation (NAT [4]) has been proposed as a means to allow global communication between hosts which use locally-significant IP addresses. NAT requires that IP addresses be mapped at address domain boundaries, either to globally significant addresses, or to local addresses meaningful in the next address domain along the packet's path. It is possible to define a version of NAT which is "local" to an addressing domain, in the sense that (locally significant) IP packets are mapped to globally significant CLNP packets before exiting a domain, in a manner which is transparent to systems outside of the domain.

NAT allows old systems to continue to be used globally without application gateways, at the cost of significant additional complexity and possibly performance costs (associated with translation or encapsulation of network packets at IP address domain boundaries). NAT does not address the problem of applications which pass around and use IP addresses internally.

The details of Network Address Translation is outside of the scope of this document.

Streamlining Operation of CLNP

CLNP contains a number of optional and/or variable length fields. For example, CLNP allows addresses to be any integral number of bytes up to 20 bytes in length. It is proposed to "profile" CLNP in order to allow streamlining of router operation. For example, this might involve specifying that all Internet hosts will use an NSAP address of precisely 20 bytes in length, and may specify which optional fields (if any) will be present in all CLNP packets. This can allow all CLNP packets transmitted by Internet hosts to use a constant header format, in order to speed up header parsing in routers. The details of the Internet CLNP profile is for further study.
