

Design and Collection of a Handwriting Sample Image Database

M. D. Garris

Advanced Systems Division

National Institute of Standards and Technology,

Gaithersburg, MD 20899

Abstract

NIST, under sponsorship from the Bureau of the Census, has collected a database consisting of 2,100 pages of binary image data of hand printed characters including numerals and text. *NIST Special Database 1* contains handwriting samples from 2,100 writers geographically distributed across the United States. NIST is currently using this database to research field-isolation, box detection and removal, character segmentation, and writer-independent neural character recognition. In addition to advancing the design of algorithms, this database and its study can aid the social sciences. Observations can be compiled and used to improve form design and field layout strategies. Region-based studies and comparisons are also possible due to regionally distributed and referenced populations of writers in the database. In creating this large database, obstacles to the effective archiving of images have been dealt with and eliminated. This paper describes the database's content in terms of its collection, organization, and usefulness. The strategies and conventions used to develop *NIST Special Database 1* can be applied to any discipline requiring the use of image archives.

1.0 Introduction

Learning-algorithms and artificially intelligent machines show great promise for use in a wide range of exciting applications. Many potential computer applications have proven to be virtually unsolvable by conventional programming techniques. Now, new programming paradigms in conjunction with high speed parallel hardware implementations have created the technology necessary to unlock many useful applications. Automated character recognition, the recognition of handprinted text, is one of the application domains experiencing great advances from these new technologies. However, the systems being developed demand more than just sophisticated software and hardware, they require large sets of statistical exemplars in order to effectively model real problems. It was the need for a large collection of handwriting samples which motivated the production of the database of handprinted characters.

2.0 Images Versus Text Archives

Improved recognition algorithms and the increased performance of computers has touched off an imaging revolution. Computer databases containing transcribed text from paper archives are now being replaced by databases generated via automated recognition from image archives. This wave of new imaging technology offers a new way of information archival, retrieval, and processing for many disciplines including the social sciences. But several key issues must be addressed to make imaging effective.

First, there is the issue of data storage. A full page of text containing 60 lines with 80 characters per line requires less than 5,000 bytes of computer memory. Image archives place a much greater demand on mass storage requirements. A single binary image of the same information at 300 dots per inch is over 1 Megabyte in size. If the gray scale image contained 256 possible different shades of gray, as opposed to only two possible values (white or black) in a binary image, the same information requiring 5,000 bytes as text now demands over 8,000,000 bytes of storage.

The storage requirements for images leads to a second issue, data compression. The feasibility and usefulness of image technologies is greatly reduced without the use of effective data compression. Standards are required to guarantee interchangeability among imaging devices and image applications. In addition to data compression conformance, there is a need for an uniform image format. A computer image is encoded as a stream of bits, 1's and 0's. This one dimensional bit stream may be encoded in many different ways depending on various host architectures. Ancillary information is required to correctly interpret the information which has been encoded. But what minimal set of image descriptors is required to guarantee maximum functionality? Much energy is being invested to standardize image formats and image compression techniques, but much more is still required[1,2].

A third issue facing the effective use of images deals with archival storage media. Today's storage options include both magnetic and optical media. If images are stored as a static archive then a read-only media such as CD-ROM or a write-once read-many (WORM) media is appropriate. However if an application requires only short term storage of images, then large read-writable magnetic disks may be appropriate. *NIST Special Database 1* provides example solutions to each of these three issues.

3.0 Database Content

NIST Special Database 1 contains 2,100 full page images of handwriting samples printed by 2,100 different writers geographically distributed across the United States with a sampling roughly proportional to population density[3]. Each page in this handwritten character database is a 300 pixels/inch image of a filled form. This image data was collected for use in training and test-

ing high speed, high throughput, recognition engines; therefore, the images were digitized as binary in order to reduce communication bandwidth and storage costs.

Each page in the database is an image of a structured form filled in by a unique writer. A single field template specifying the number of entry fields, their size and location, was used. An image of one of the blank forms used in the database is shown in Figure 1. The form is comprised of 3 identification boxes, 28 numeral boxes, 2 alphabetic boxes, and 1 unconstrained text paragraph box. This structured form layout provides a total character count of over 1,000,000 characters in the database; about 300,000 numerals and 700,000 alphabetic characters. In addition to the primary form images, 33 isolated sub-images of the boxes on each primary page, excluding the name field, are included accounting for 71,400 individual images in the entire database. With an individual form image requiring approximately 1 Megabyte of memory, the total image database, in uncompressed form, occupies approximately 3 Gigabytes of mass-storage. Therefore, the images are 2-dimensionally compressed in accordance with CCITT Group 4 [2], reducing the overall size of the database to under 700 Megabytes.

Figure 1 and Figure 2 about here

4.0 Handwriting Sample Form Layout

Figure 2 displays an actual form from the database. Each entry field on this form is represented as a box. The writers in the database have been made anonymous by blacking out the name field. The string of machine printed information above each box instructed the writer what to print in the box. The instructions on the form requested that the writer print the information provided above each box within the box. Assuming the writer followed the directions and correctly completed the form, each box is self-referenced. This method of collection reduces the overall cost incurred by eliminating the need for transcribing the printed samples by hand. The instructions do not specify what writing implement should be used. Therefore, the database contains a random assortment of pencils and pens resulting in handwriting samples varying in width, contrast, and color.

Careful planing went into the design of this form. The form strategy applied was developed in order to ensure successful data capture based on current forms processing techniques. Every field is consistently defined as a bold box explicitly defining the location and spatial extent of each field. The single line boxes are 7mm in height giving writers ample room to fit entire characters within the box. This served to minimally constrain the writer's print but more importantly aids the automated field isolation within the recognition system. By using a consistent field demarcation such as a rectangular box, a single software or hardware solution can be implemented to locate every field on the form. The boxes on this form are maximally spaced in an attempt to

minimize crowding and clutter. The more cluttered a form layout, the more difficult it becomes for a computer to locate and identify fields thereby increasing the potential for recognition failures. This implies a trade-off between minimizing the amount of paper handled by increasing the amount of data entered on each page versus lower recognition rates due to increased clutter and increased recognition confusion.

Ignoring the first 3 identification boxes shown in Figure 2, as one scans down the form, there is a progression of increasing recognition difficulty. The first series of boxes are comprised of digits only, followed by boxes comprised of alphabetic characters. There are only 10 unique classes of digits, '0' through '9', versus 26 possible classes of the alphabetic characters, 'A' through 'Z'. The reduced size of possible classes makes the recognition of numeric character fields easier than the recognition of alphabetic fields which in turn are easier to recognize than alphanumeric fields. There also is a progression down the form of increased character segmentation difficulty. The segmentation of lower case characters is challenging because extenders on the characters, 'g', 'j', 'p', 'q', and 'y', often extend beyond the bottom of the box. The Constitution box, the last box on the form, pushes the outer limits of current segmentation and recognition technology due to the handwriting being unconstrained; no specified line breaks designated, no form lines to guide the writer left to right, no form lines to constrain the height of the characters, etc.

There are 50 variations of the form layout in the database. As stated above, a single field template was used so that all 2,100 forms contain the same number of boxes, each of the same size and relative location. The variations are realized in the information provided above each box. Every form requested that the writer print the sequence of digits, 0 through 9, three times in boxes 3, 4, and 5. Depending on the form variation, the digits in boxes 6 through 30 vary, however the number of digits in each box remain fixed. The variations in forms provide 50 different random orders of the lower case alphabet and 50 different random orders of the upper case alphabet across the 2,100 forms.

5.0 Database Acquisition

The 50 form layout variations were tightly specified using a type setting software package and printed on a laser printer. The 50 templates were then massively reproduced with a photocopier. From copies of the original 50 variations, 3,400 blank forms were mailed to 12 regional offices within the Bureau of the Census. There, the forms were filled out by field data takers and returned via business return envelopes. This process greatly reduced administrative and mailing overhead expenses while providing a sampling roughly proportional to geographic population distributions within the United States. Figure 3 illustrates the 12 different Census regions.

Figure 3 about here

Out of 3,400 forms mailed to the regional offices, 2,100 completed forms were returned. From August 1989 through October 1989, the forms received at NIST were sequentially indexed, sorted according to region, logged, and digitized. Figure 4 lists the information recorded in the historical log provided with the database. Included is the form identification index, the form variation type (1 of 50), the date received and processed at NIST, the assumed writing implement used in completing the form, the color of the implement's ink or lead, and a subjective quality rating.

Figure 4 about here

6.0 Image File Format

As stated in the introduction, image file formats and effective data compression and decompression are critical to the usefulness of image archives. Each page returned was digitized in binary form at 300 dots per inch, 2-dimensionally compressed using CCITT Group 4, and temporarily archived onto computer magnetic mass storage. Once all forms were digitized, the images were mastered and replicated onto ISO-9660 formatted CD-ROM discs for permanent archiving and distribution.

In this application, a raster image is a digital encoding of light reflected from discrete points on a scanned form. The 2-dimensional area of the form is divided into discrete locations according to the resolution of a specified grid. Each cell of this grid is represented by a single bit value 0 or 1 called a pixel; 0 represents a cell predominately white, 1 represents a cell predominately black. This 2-dimensional sampling grid is then stored as a 1-dimensional vector of pixel values in raster order; left to right, top to bottom. Successive scan lines (top to bottom), contain the values of a single row of pixels from the grid concatenated together.

After digitization, certain attributes of an image are required to correctly interpret the 1-dimensional pixel data as a 2-dimensional image. Examples of such attributes are the pixel width and pixel height of the image. These attributes can be stored in a machine readable header prefixed to the raster bit stream. A program which is used to manipulate the raster data of an image, is able to first read the header and determine the proper interpretation of the data which follows it. Figure 5 illustrates this file format.

Figure 5 about here

NIST has designed, implemented, and distributed images based on this paradigm. A header format named IHead has been developed for use as an image interchange format. Numerous

image formats exist; some are widely supported on small personal computers, others supported on larger workstations; most are proprietary formats, few are public domain. IHead is an attempt to design an open image format which can be universally implemented across heterogeneous computer architectures and environments. Both documentation and source code for the IHead format are publicly available. IHead has been designed with an extensive set of attributes in order to: adequately represent both binary and gray level images; represent images captured from different scanners and cameras; and satisfy the image requirements of diversified applications, including but not limited to, image archival/retrieval, character recognition, and fingerprint classification.

IHead has been successfully ported and tested on several systems including: UNIX workstations and servers, DOS personal computers, and VMS mainframes. The attribute fields in IHead can be loaded into main memory in two distinct ways. Since the attributes are represented by the ASCII character set, the attribute fields may be parsed as null-terminated strings, an input/output format common in the 'C' programming language. IHead can also be read into main memory using record-oriented input/output. The fixed length of the header is prefixed to the front of the header as shown in Figure 5. The IHead structure definition written in the 'C' programming language is listed in Figure 6.

Figure 6 about here

Figure 7 lists the header values from an IHead file corresponding to the structure members listed in Figure 6. This header information belongs to the isolated box image displayed in Figure 8. Referencing the structure members listed in Figure 6, the first attribute field of IHead is the identification field, **id**. This field uniquely identifies the image file, typically by a file name. The identification field in this example not only contains the image's file name, but also the reference string the writer was instructed to print in the box. The reference string is delimited by double quotes. This convention enables an image recognition system's hypothesized answers to be automatically scored against the actual characters printed in the box.

Figure 7 and Figure 8 about here

The attribute field, **created**, is the date on which the image was captured or digitized. The next three fields hold the image's pixel **width**, **height**, and **depth**. A binary image has a pixel depth of 1 whereas a gray scale image containing 256 possible shades of gray has a pixel depth of 8. The attribute field, **density**, contains the scan resolution of the image; in this case, 300 dots per inch. The next two fields deal with compression.

In the IHead format, images may be compressed with virtually any algorithm. Whether the image is compressed or not, the IHead is always uncompressed. This enables header interpreta-

tion and manipulation without the overhead of decompression. The **compress** field is an integer flag which signifies which compression technique, if any, has been applied to the raster image data which follows the header. If the compression code is zero, then the image data is not compressed, and the data dimensions: width, height, and depth, are sufficient to load the image into main memory. However, if the compression code is nonzero, then the **complen** field must be used in addition to the image's pixel dimensions. For example, the image described in Figure 7 has a compression code of 2. This signifies that CCITT Group 4 compression has been applied to the image data prior to file creation. In order to load the compressed image data into main memory, the value in **complen** is used to load the compressed block of data into main memory. Once the compressed image data has been loaded into memory, CCITT Group 4 decompression can be used to produce an image which has the pixel dimensions consistent with those stored in its header. Using CCITT Group 4 compression and this compression scheme on the images in this database, a compression ratio of 20 to 1 was achieved.

The attribute field, **align**, stores the alignment boundary to which scan lines of pixels are padded. Pixel values of binary images are stored 8 pixels (or bits) to a byte. Most images, however, are not an even multiple of 8 pixels in width. In order to minimize the overhead of ending a previous scan line and beginning the next scan line within the same byte, a number of padded pixels are provided in order to extend the previous scan line to an even byte boundary. Some digitizers extend this padding of pixels out to an even multiple of 8 pixels, other digitizers extend this padding of pixels out to an even multiple of 16 pixels. This field stores the image's pixel alignment value used in padding out the ends of raster scan lines.

The next three attribute fields identify binary interchanging issues among heterogeneous computer architectures and displays. The **unitsize** field specifies how many contiguous pixel values are bundled into a single unit by the digitizer. The **sigbit** field specifies the order in which bits of significance are stored within each unit; most significant bit first or least significant bit first. The last of these three fields is the **byte_order** field. If **unitsize** is a multiple of bytes, then this field specifies the order in which bytes occur within the unit. Given these three attributes, binary incompatibilities across computer hardware and binary format assumptions within application software can be identified and effectively dealt with.

The **pix_offset** attribute defines a pixel displacement from the left edge of the raster image data to where a particular image's significant image information begins. The **whitepix** attribute defines the value assigned to the color white. For example, the binary image described in Figure 7 is black text on a white background and the value of the white pixels is 0. This field is particularly useful to image display routines. The **issigned** field is required to specify whether the units of an image are signed or unsigned. This attribute determines whether an image with a pixel depth of 8,

should have pixels values interpreted in the range of -128 to +127, or 0 to 255. The orientation of the raster scan may also vary among different digitizers. The attribute field, **rm_cm**, specifies whether the digitizer captured the image in row-major order or column-major order. Whether the scan lines of an image were accumulated from top to bottom, or bottom to top, is specified by the field, **tb_bt**, and whether left to right, or right to left, is specified by the field, **rl_lr**.

The final attributes in IHead provide a single historical link from the current image to its parent image; the one from which the current image was derived or extracted. In Figure 7, the **parent** field contains the full path name to the image from which the image displayed in Figure 8 was extracted. The **par_x** and **par_y** fields contain the origin, upper left hand corner pixel coordinate, from where the extraction took place from the parent image. These fields provide a historical thread through successive generations of images and subimages. We believe that the IHead image format contains the minimal amount of ancillary information required to successfully manage binary and gray scale images.

7.0 Database Examples and Observations

NIST Special Database 1 embodies a wide range of handwriting styles. The completed forms in this database illustrate the difficulty in recognizing handprinted characters with a computer. Frequently, even humans can not positively identify characters without confirming their best guesses against the font information printed on the forms above each box. A quick scan of these handwriting samples shows great variation in size, slant, contrast, spacing, shape, the random interchanging of upper and lower case, and the random switching between print and cursive script.

7.1 Examples of Handwriting Extremes

In this section, a select set of handwriting samples from the database are shown in an attempt to illustrate to the reader the extreme variation in handwriting existing between different writers. The first form shown in Figure 2 illustrates neat and very legible print. If all handprint were of this style and quality, the challenge of recognizing handprint would no longer exist.

Figure 9 about here

Compare the handprint in Figure 2 to the sample shown in Figure 9. The quality of handprint in the second figure is dramatically lower. Especially notice how the quality of the writing degrades from left to right, top to bottom, within the Constitution box. The characters in the top left corner of this box are well spaced both horizontally and vertically and appear reasonably legible. As the writer became cramped for space at the end of lines and towards the bottom of the box, the restriction of space visibly impacted the neatness and readability of the person's writing.

Figure 10 shows an example of a person's handprint written with a pronounced slant. It is interesting to note how the slant of characters from this writer varies. The characters printed in the digit boxes contain substantial slant, but when the person printed within the unconstrained Constitution box, the slant is even more pronounced. It is curious how the slant is almost completely missing from the characters printed in the two alphabetic boxes.

Figure 10 about here

The average size of characters between writers also greatly varies. Figure 11 contains a sample of handprint which is relatively tall. If this person wrote any taller, the characters would not remain within the boxes. Notice how the writer's lower case extenders on the 'g', 'y', 'q', 'p', and 'j' all extend well below the bottom of the lower case alphabet box. In contrast to tall print, Figure 12 shows a portion of a form containing extremely small handprinted characters. Here the writer's handprint is almost the same size as the machine printed information on the form.

Figure 11 and Figure 12 about here

In this database, the writers were not told what writing implement should be used to fill in the form. Therefore, the forms in this database represent different hardness of pencils, different colored ink pens, and different pen tips. A static scanner setting was used to digitize all the forms in the database regardless of the contrast between a form's background and the handprinted information it contains. The result is a database of images varying greatly in image quality or contrast. An example of a box completed using a hard lead pencil is shown in Figure 13. The characters in this image are barely readable, some are not. Notice how the individual characters are breaking up. Most character recognition systems would have significant problems reading this image. On the other hand, Figure 14 shows a section of a form which was completed using a broad felt tipped pen. In this image, the pen strokes are extremely wide causing most interior holes in characters to be closed. Notice how difficult it is to distinguish 3's from 8's on this form.

Figure 13 and Figure 14 about here

7.2 Other Sources of Handprint Variations

Two other types of handprint variations are included in this database. It has been observed that writers frequently make no distinction when printing lower and upper case letters. Also, writers tend to randomly mix handprint with cursive script. Figure 15 shows a section of a form completed by a writer which printed nearly every lower case letter in the lower case alphabetic box the same way as the upper case letters were printed. Notice how the writer of this form printed within the alphabetic boxes, but switched completely to cursive script when filling in the Constitution box. In Figure 16, the two boxes illustrate a writing style in which the writer printed all characters

in the lower case alphabetic box as cursive and filled in the upper case alphabetic box with printed letters. A robust recognition system must account for these inconsistencies.

Figure 15 and Figure 16 about here

7.3 Measurements Acquired During Processing

Robust document recognition systems detect and account for form rotation within an image. NIST has developed an automated data capture system based on the forms in *NIST Special Database 1*. This hybrid system combines traditional image processing, biologically motivated image filtering, and neural networks on a massively parallel machine. One component in this system identifies form rotation and normalizes the image appropriately. The database contains images of forms rotated between +1.45 degrees and -2.23 degrees with an average of 0.3 degrees.

This rotation was introduced at two different points in time. First, the original 50 form variants were reproduced using a photocopier. This introduced small rotational variations in the pages produced by the photocopier. The second source of rotational noise was introduced during the scanning of the completed forms. Note that despite the tight controls NIST placed on the printing, reproducing, and scanning of these forms, significant rotational noise exists in the database. Figure 17 shows an image from the database of a form with substantial rotational noise.

Figure 17 about here

7.4 Analysis of Boxes Left Empty

In addition to advancing the design of recognition algorithms, *NIST Special Database 1* can be used to aid the social sciences as well. For example, out of 69,300 boxes across the 2,100 filled forms, 151 boxes were skipped and left empty with nearly 40% of these boxes corresponding to a single 2-character box found at the end of a line in the same location on all forms. This box is referenced as box 15 according to the labels assigned in Figure 1. An example is shown in Figure 18. Apparently in a writer's haste to finish the form, he or she overlooked this small context box. This box was skipped a total of 58 times in this database. The next two most frequently skipped boxes were the two alphabetic boxes. The upper case alphabetic box was left empty 15 times while the lower case alphabetic box was left empty only 9 times. These two boxes are the most difficult to copy on the entire form. The number of times the alphabetic boxes were left empty even when combined is much less than the number of times box 15 was skipped. Observations like this one can be compiled and used to improve form design and field layout strategies.

Figure 18 about here

8.0 Conclusion

NIST Special Database 1 proves to be a practical example of how issues such as image format, image data compression, and archival media need to be addressed. NIST is currently using this database to research field-isolation, box detection and removal, character segmentation, and writer-independent biologically motivated neural character recognition. Through the use of this database resource, handwritten character recognition with greater than 96% accuracy has been achieved in NIST laboratories on test sets of over 1,000 arbitrarily chosen character digits with a classification rate of 10 ms per character[4,5]. Based on this database, NIST is currently developing a draft standard on methods for evaluating the performance of systems intended to recognize handprinted characters from image data scanned from forms. To date, over 50 copies of the database have been distributed to universities, private companies, and to government agencies. This includes 10 different universities and 40 different computer companies and recognition laboratories within 8 different countries. *NIST Special Database 1* is the largest collection of handprinted characters publicly available for recognition system testing.
