Abstract

The study of topological quantum field theories increasingly relies upon concepts from higher-dimensional algebra such as n -categories and n -vector spaces. We review progress towards a definition of n -category suited for this purpose, and outline a program in which n -dimensional TQFTs are to be described as n -category representations. First we describe a ‘suspension’ operation on n -categories, and hypothesize that the k -fold suspension of a weak n -category stabilizes for $k \geq n + 2$. We give evidence for this hypothesis and describe its relation to stable homotopy theory. We then propose a description of n -dimensional unitary extended TQFTs as weak n -functors from the ‘free stable weak n -category with duals on one object’ to the n -category of ‘ n -Hilbert spaces’. We conclude by describing n -categorical generalizations of deformation quantization and the quantum double construction.

Introduction

One important lesson we have learned from topological quantum field theory is that describing dynamics using *group* representations is only a special case of describing it using *category* representations. In fact, examining the structure of the known n -dimensional topological quantum field theories, it appears that many are representations of some sort of n -category. While a category is a structure with objects and morphisms between these objects, in an n -category there are also ‘morphisms between morphisms’ or 2-morphisms, ‘morphisms between 2-morphisms’ or 3-morphisms, and so on, up to n -morphisms. In the theory of manifolds, k -morphisms correspond to manifolds (with boundary, corners, etc.) of dimension k .

The theory of n -categories is one of several related approaches to describing topology in purely algebraic terms. Taken together, these constitute a subject known as

‘higher-dimensional algebra’. While the basic insights of this subject are simple and beautiful, it is far from reaching its final form. The aim of this paper is to paint, in rather broad strokes, a picture of some patterns that are becoming apparent. In many cases these are only well-understood in low dimensions. The topology of higher dimensions is known to be very different, so uncautious extrapolation is risky. Nonetheless, the patterns we see so far should serve as a useful guide to research, if only to goad us to a better understanding — and in particular, an *algebraic* understanding — of the relation between topological quantum field theory and the traditional techniques of algebraic topology, which work in arbitrarily high dimensions.

In the rest of this section we review some of the physics issues addressed by topological quantum field theories (TQFTs), and recall the mathematical definition of a TQFT. In Section 2, we give a sketchy overview of why n -categories should serve as a natural framework for an algebraic approach to TQFTs. In Section 3 we recall the definition of a ‘strict n -category’, and in Section 4 we begin to explain why a weakening of this notion is crucial — though only well-understood for $n \leq 3$. In Section 5 we describe how to ‘suspend’ an n -category, and argue that the process of iterated suspension of an n -category should stabilize after $n + 2$ times. In Section 6 we recall the roots of higher-dimensional algebra in algebraic topology, and explain how our notion of suspension relates to that in homotopy theory. In Section 7 we argue that an algebraic framework for smooth manifold theory of dimension $\leq n$ is given by the ‘free stable n -category with duals on one object’. In Section 8 we then argue that a unitary extended n -dimensional TQFT is a representation of this n -category in the n -category of ‘ n -Hilbert spaces’. In Section 9 we conclude with some examples illustrating the role of ‘quantization’ in higher-dimensional algebra. Since we wish to assume a minimum of familiarity with the subject, we take a rather expository approach, and frequently refer the reader to review articles and books rather than original papers. For this reason, our bibliography is by no means complete.

Why are TQFTs interesting as *physics*? One reason is that they possess certain features one expects of a quantum theory of gravity. This is not to say that quantum gravity is, or will be, a TQFT. Nonetheless, to understand the significance of TQFTs, it is useful to recall some ideas from quantum gravity.

The ‘general covariance’ or ‘diffeomorphism-invariance’ of general relativity is often regarded as a crucial feature to be preserved, if possible, by any quantum theory accommodating gravity. However, it has traditionally been a bit unclear what we really are asking for when we say we want a theory to be generally covariant. In Einstein’s original work on general relativity [30], he emphasized that the equations should preserve their form under arbitrary coordinate transformations: “*The general laws of nature are to be expressed by equations which hold good for all systems of coordinates, that is, are covariant with respect to any substitutions whatever (generally covariant).*”

Later, it became clear that this definition of general covariance is vacuous without some restriction on how the quantities involved in the laws transform under coordinate

transformations. The importance of *tensors* and their transformation rules is often stressed. In fact, requiring all the quantities in a field theory to be tensors misses the point in at least two ways. On the one hand, modern field theories typically make use of nontensorial objects such as spinor fields, connections, and other bundle sections. (Note that connections can be regarded as bundle sections with the aid of jet bundles.) On the other hand, special-relativistic classical field theories on Minkowski space, which we normally do not think of as ‘generally covariant,’ can nonetheless be reformulated as diffeomorphism-invariant, purely tensorial equations by coupling them to Einstein gravity, setting the gravitational constant equal to zero, and then adding an extra equation saying that the metric is flat!

Reflection along these lines led to the recognition that the key feature distinguishing general relativity from previous theories is actually its lack of a fixed prior geometry. In the words of Misner, Thorne and Wheeler [63], “By ‘*prior geometry*’ one means any aspect of the geometry of spacetime that is fixed immutably, i.e., that cannot be changed by changing the distribution of gravitating sources.” The best-known example of prior geometry is the Minkowski metric in special relativity. In special-relativistic quantum field theory, dynamics is described in terms of representations of the symmetry group of this metric, that is, the Poincaré group. Note that even in the diffeomorphism-invariant reformulation of special-relativistic field theory described above, there is, for each solution of the equations of motion, a canonical choice of a subgroup of the diffeomorphism group isomorphic to the Poincaré group: the isometry group of the metric.

More generally, while *sufficient* conditions for a theory to lack prior geometry are difficult to state, it certainly seems *necessary* that there be no canonical way to choose, for each state of the theory, a subgroup of the spacetime diffeomorphism group isomorphic to some fixed nontrivial Lie group. For, by the Erlangen philosophy that a geometry is known by its group of symmetries, such a subgroup would indicate the presence of prior geometry independent of the state. This, in turn, suggests that in theories without prior geometry, dynamics will not be described in terms of the representations of a Lie group of spacetime symmetries.

The question is then, how *is* dynamics described in such theories? This is known as the ‘problem of time’. In canonical quantum gravity on a spacetime of the form $\mathbf{R} \times S$, it is manifested by the fact that physical states should satisfy the Wheeler-DeWitt equation

$$H\psi = 0,$$

expressing their invariance under the diffeomorphism group. This gives rise to the so-called ‘inner product problem’, namely: what is the correct inner product on the space of states? In quantum theories with prior geometry, the inner product is chosen so that spacetime symmetry group acts unitarily on the space of states, but in a formalism where states are diffeomorphism-invariant the inner product must be determined in some other way.

Many different approaches have been proposed to both these problems [3, 41],

but here we only consider one, namely Atiyah's definition of a TQFT [4]. This is in fact a very radical approach! First, rather than attempting to describe the dynamics of fields on a single spacetime manifold, a TQFT describes the dynamics of fields in terms of a category in which the objects are $(n - 1)$ -dimensional manifolds representing possible choices of 'space', and morphisms are n -dimensional cobordisms representing choices of 'spacetime'. In fact, a TQFT is a kind of a representation of this category, assigning a vector space of states to each object and a linear operator to each morphism. Second, in any unitary TQFT satisfying a certain nondegeneracy condition, the structure of this category automatically determines the inner product in the space of states for any $(n - 1)$ -manifold.

To fully appreciate these ideas one must recognize that a group is just a very special sort of category. Recall that a category consists of a collection of objects, and for any objects x and y , a set $\text{hom}(x, y)$ of morphisms from x to y . (Technically, we are considering only locally small categories.) If $f \in \text{hom}(x, y)$, we write $f: x \rightarrow y$. Morphisms $g: x \rightarrow y$ and $f: y \rightarrow z$ can be composed to obtain a morphism $fg: x \rightarrow z$, and composition is associative. Moreover, for every object x there is a morphism $1_x: x \rightarrow x$ acting as the identity for composition. It follows that all the structure of a category with a single object x can be summarized by saying that $\text{hom}(x, x)$, is a *monoid*: a set equipped with an associative product and identity element. Loosely, we say that a category with only one object is a monoid. Similarly, a category with only one object and all morphisms invertible is a group.

Recall also that given two categories C and D , a functor $F: C \rightarrow D$ maps objects of C to objects of D and morphisms of C to morphisms of D in a structure-preserving manner. In other words, $f: x \rightarrow y$ implies $F(f): F(x) \rightarrow F(y)$, and also $F(fg) = F(f)F(g)$ and $F(1_x) = 1_{F(x)}$. Thinking of a group as a one-object category G , a group representation is thus just a functor from G to Vect , the category whose objects are (finite-dimensional) vector spaces and morphisms are linear maps. This leads us to define a 'representation' of a category C to be a functor from C to Vect .

An n -dimensional TQFT is a certain sort of representation of the category $n\text{Cob}$ of n -dimensional cobordisms. This category has compact oriented $(n - 1)$ -manifolds as objects, and oriented cobordisms between such manifolds as morphisms. Composition of cobordisms is given by gluing as shown in Figure 1. The identity 1_M for any object M is represented by the cylinder $[0, 1] \times M$. In what follows we will often abuse language and identify cobordisms with the manifolds with boundary representing them, but it is important to keep in mind the distinction: for example, composition is not strictly associative, but only associative up to equivalence, unless we treat cobordisms carefully [67].

A representation of $n\text{Cob}$ is thus a functor $Z: n\text{Cob} \rightarrow \text{Vect}$. The fact that Z assigns to the cylindrical spacetime $[0, 1] \times M$ the identity on $Z(M)$, that is, the trivial time evolution operator, corresponds to the Wheeler-DeWitt equation. The dynamics of the theory only becomes evident upon considering nontrivial cobordisms.

1. Composition in $n\text{Cob}$

The category $n\text{Cob}$ is not merely a category; it has extra structures in common with Vect , and the definition of a TQFT requires that the functor $Z: n\text{Cob} \rightarrow \text{Vect}$ preserve these extra structures. In fact, these extra structures are important clues about the nature of higher-dimensional algebra.

First, both $n\text{Cob}$ and Vect are ‘monoidal’ categories. For precise definitions of this and other terms from category theory, see Mac Lane [57]; roughly speaking, a category is monoidal if it has tensor products of objects and morphisms satisfying all the usual axioms, and an object 1 playing the role of identity for the tensor product. In $n\text{Cob}$, the tensor product is given by disjoint union, as shown in Figure 2, and the identity is the empty set. In Vect , the tensor product is the usual tensor product of vector spaces, which has \mathbf{C} as its identity. In a TQFT, the functor $Z: n\text{Cob} \rightarrow \text{Vect}$ is required to be ‘monoidal’, that is, to preserve tensor products and to send the identity object in $n\text{Cob}$ to the identity object in Vect .

2. Tensor product in $n\text{Cob}$

Second, both $n\text{Cob}$ and Vect are ‘symmetric’ monoidal categories. In a symmetric monoidal category, there is for any pair of objects x, y a natural isomorphism, the ‘braiding’,

$$B_{x,y}: x \otimes y \rightarrow y \otimes x,$$

which is required to satisfy various axioms including the symmetry equation

$$B_{y,x}B_{x,y} = 1_{x \otimes y}.$$

In $n\text{Cob}$, the symmetry $B_{x,y}$ is a cobordism of the sort shown in Figure 3. In Vect , the symmetry is the usual isomorphism of vector spaces $x \otimes y$ and $y \otimes x$.

3. Symmetry in $n\text{Cob}$

Third, both $n\text{Cob}$ and Vect are ‘rigid’ monoidal categories. These are monoidal categories in which every object x has a ‘dual’ x^* , and there are ‘unit’ and ‘counit’ maps

$$i_x: 1 \rightarrow x \otimes x^*, \quad e_x: x \otimes x^* \rightarrow 1 \quad (1)$$

satisfying various axioms including the triangle identities, which say that the following diagrams must commute:

$$\begin{array}{ccc}
 x & \xrightarrow{1_x} & x \\
 & \searrow^{i_x \otimes 1_x} & \nearrow_{1_x \otimes e_x} \\
 & x \otimes x^* \otimes x &
 \end{array}$$

$$\begin{array}{ccc}
 x^* & \xrightarrow{1_x} & x^* \\
 & \searrow_{1_{x^*} \otimes i_x} & \nearrow_{e_x \otimes 1_{x^*}} \\
 & x^* \otimes x \otimes x^* &
 \end{array}$$

(For ease of exposition, we demand one extra axiom besides the usual ones, namely that in the symmetric case the natural morphism from x to x^{**} corresponding to the ‘twist’ in Figure 31 be the identity.) In $n\text{Cob}$, x^* is the manifold x equipped with the opposite orientation. The unit and counit are the cylinders shown in Figure 4, where we also depict the triangle identities.

4. Unit, counit, and triangle identities in $n\text{Cob}$

In short, a TQFT is a rigid symmetric monoidal functor $X: n\text{Cob} \rightarrow \text{Vect}$, that is, one preserving the rigid symmetric monoidal structure. Now the category Hilb , whose objects are (finite-dimensional) Hilbert spaces and whose morphisms are linear maps, is also rigid symmetric monoidal. A ‘unitary’ TQFT is a rigid symmetric monoidal functor $Z: n\text{Cob} \rightarrow \text{Hilb}$ which is also compatible with a second sort of duality structure. The operation $\dagger: n\text{Cob} \rightarrow n\text{Cob}$ taking each object to itself and taking each cobordism $f: x \rightarrow y$ to the orientation-reversed cobordism $f^\dagger: y \rightarrow x$ is a contravariant functor, that is, $1_x^\dagger = 1_x$ and $(fg)^\dagger = g^\dagger f^\dagger$. There is also a contravariant functor $\dagger: \text{Hilb} \rightarrow \text{Hilb}$ taking each object to itself and taking each linear map $f: x \rightarrow y$ to the Hilbert space adjoint $f^\dagger: y \rightarrow x$. A unitary TQFT must satisfy $Z(f^\dagger) = Z(f)^\dagger$ for all morphisms f . Given cobordisms f and g from the empty set to x , the inner product of the vectors $Z(f)1$ and $Z(g)1$ is then given by $Z(f^\dagger g)1$. If $Z(x)$ is spanned by vectors of this form, the inner product in $Z(x)$ is thus determined by Z .

To conclude, it is crucial to note that Atiyah never propounded the notion of a TQFT as a panacea for the problems of quantum field theories without prior geometry. Indeed, the TQFTs we understand so far appear to reduce in the classical limit to field theories with no local degrees of freedom, that is, for which all solutions are *locally* physically equivalent. One does not expect a realistic theory of quantum gravity to have this property. Indeed, while there are many clues indicating that quantum gravity is closely *related* to known TQFTs [6], it may be an inherently more complex sort of theory. Ideas from higher-dimensional algebra, however, may still be very useful [5].

Cobordisms

While it is customary to begin in field theory by writing down a Lagrangian, the most efficient ways to construct TQFTs tend to be algebraic in flavor. Since a TQFT is a rigid symmetric monoidal functor from $n\text{Cob}$ to Vect , one can begin by describing $n\text{Cob}$ as a rigid symmetric monoidal category in terms of generators and morphisms. Here the ‘generators’ are morphisms from which one can obtain *all* the morphisms by the operations present: composition, tensor product, the symmetry, and duals. Then, to actually construct a TQFT, one merely needs to assign objects and morphisms in Vect to all of the generators of $n\text{Cob}$, and check that the relations hold.

How does one determine generators and relations for $n\text{Cob}$? Assuming momentarily that we already understand the *objects* in $n\text{Cob}$ and their automorphisms, we can obtain generators for the remaining *morphisms* using Morse theory [62]. A cobordism from M to M' can be represented as an n -manifold N having boundary identified with $\overline{M} \cup M$. If we put a ‘height’ function on N — a smooth real function F with $F|_M = 0$ and $F|_{M'} = 1$ — generically it will be a Morse function. That is, it will have

only nondegenerate critical points p_i , occurring at distinct levels $F(p_i) = t_i$. Slicing N along level sets of F between the critical levels t_i amounts to factoring our cobordism as a product of simple ‘generating’ cobordisms, as shown in Figure 5.

5. Describing a cobordism using Morse theory

We can visualize the result as a ‘movie’ of N in which each ‘frame’ is obtained from the previous one by attaching a j -handle — that is, cutting out a copy of $D^{n-j-1} \times S^{j-1}$ and gluing in a copy of $S^{n-j} \times D^j$ — where j is the number of negative eigenvalues of the Hessian of F at the intervening critical point. These basic processes are shown for $n = 2$ in Figure 6; the cases $j = 0, 1, 2$ are called the birth of a circle, the death of a circle, and the saddle point, respectively.

6. Handle attachments for $n = 2$

Of course, the manifold N admits many different Morse functions, so the cobordism it represents can be expressed in many different ways as the product of a series of handle attachments. However, given two Morse functions F_0 and F_1 , we can interpolate between them by a smooth family of functions F_s . Generically, the functions F_s will be Morse functions except for finitely many values s_i at which the level of one critical point passes another, two critical points coalesce, or a critical point splits in two. The study of these generic paths between Morse functions is known as Cerf theory [19, 50]. In the same sense as which handle attachments give *generators* for $n\text{Cob}$, these paths between Morse functions give *relations*, known as handle slides and cancellations. We can visualize these as ‘movie moves’ going between two different movies of the same cobordism. An example of a handle cancellation for the $n = 2$ case is shown in Figure 7.

7. A handle cancellation for $n = 2$

For the case $n = 1$ it is easy to use these ideas to give a purely algebraic description of $n\text{Cob}$. It is (up to the standard notion of equivalence of categories) just the free rigid symmetric monoidal category on one object x ! The object x corresponds to the positively oriented point. As shown in Figure 8, the unit and counit

$$i_x: 1 \rightarrow x \otimes x^*, \quad e_x: x^* \otimes x \rightarrow 1,$$

correspond to the two types of handle attachments, namely the birth and the death of an S^0 (a pair of oppositely oriented points).

8. Handle attachments for $n = 1$

Similarly, as shown in Figure 9, the triangle identities correspond to handle cancellations.

9. Handle cancellations for $n = 1$

This simple result indicates that the rigid symmetric monoidal structure captures all the essential aspects of $n\text{Cob}$ for $n = 1$. It is tempting to seek similar purely algebraic presentations of $n\text{Cob}$ in higher dimensions. For $n = 2$ we can achieve this using the principle of ‘internalization’. In its simplest form, this amounts to the fact that any algebraic structure definable using commutative diagrams in the category Set can be generalized to categories sufficiently resembling Set . For example, a monoid

can be defined as an object x in Set equipped with a product $m: x \times x \rightarrow x$ and unit $i: 1 \rightarrow x$ making various diagrams commute. Here 1 denotes any one-element set, and we use the standard trick of thinking of the identity element of x as the image of a map $i: 1 \rightarrow x$. We can generalize the definition to any monoidal category \mathcal{C} , replacing \times with the tensor product in \mathcal{C} and 1 with the identity object of \mathcal{C} , thus obtaining the notion of a ‘monoid object’ in \mathcal{C} . For example, a monoid object in Vect is an algebra. It turns out that 2Cob is the ‘free rigid symmetric monoidal category on one commutative monoid object with nondegenerate trace’. The object in question is S^1 , and the product, identity, and trace $\text{tr}: S^1 \rightarrow 1$ are shown in Figure 10, This result yields a complete classification of 2-dimensional TQFTs [26, 68].

10. S^1 as a commutative monoid object with nondegenerate trace

Moving to higher dimensions, the best presentations of 3Cob for the purposes of constructing TQFTs are based on the Kirby calculus [50, 66, 67]. While very algebraic in flavor, these have not yet been distilled to a statement comparable to those for 1Cob and 2Cob . The Kirby calculus also gives a description of 4Cob which has yielded a few TQFTs so far [15, 52]. For $n \geq 6$ the theory of cobordisms becomes more closely tied to homotopy theory, due to the h -cobordism theorem [61]. Also, while we will not go into it here, it is important to note the existence of a theory of piecewise-linear (PL) manifolds paralleling the smooth theory [10, 21, 23, 36, 64]. The smooth and PL versions of $n\text{Cob}$ are equivalent for $n \leq 6$, but not in general for larger n .

What we seek, however, is a unified algebraic framework for this entire collection of results, one that applies to all dimensions and explains the fascinating relationships between results in neighboring dimensions. Such a framework should clarify the existing TQFT constructions, which appear at first to rely on miraculous analogies between topology and algebra, and it should aim at a classification of TQFTs. We suggest that n -category theory will provide such a framework. The reason is quite simple. We sketched how to go about a ‘generators and relations’ description of the morphisms for $n\text{Cob}$ assuming we already had a description of the objects and their automorphisms, but for higher n these grow more complicated to describe as well. Note however that in describing an n -dimensional manifold as a ‘movie’, each ‘frame’, being an $(n - 1)$ -manifold, can itself be regarded a ‘movie’ of one lower dimension, as shown in Figure 11. In other words, each object in $n\text{Cob}$ gives a morphism in $(n - 1)\text{Cob}$. A fully algebraic description of $n\text{Cob}$ should therefore involve objects,

morphisms between objects, 2-morphisms between morphisms, and so on, up to n -morphisms. We may loosely call any such structure an n -category.

11. Frames as movies of one lower dimension

If we take the objects of our n -category to be 0-manifolds, and the morphisms to be 1-manifolds with boundary, the most general sort of 2-morphism will be some kind of 2-manifold with corners, as shown in Figure 12.

12. 2-manifold with corners as 2-morphism between 1-manifolds with boundary

This is a considerable nuisance, since as n increases it becomes more and more difficult to specify a precise class of ‘ n -manifolds with corners’ and precise recipes for composing them. However, this added complexity is of vital importance, since it permits the definition of an ‘extended’ TQFT, one which behaves well under the extra cutting and pasting constructions available in this context. Heuristic reasoning involving path integrals suggests that the TQFTs described in terms of local Lagrangians should be of this extended sort, and so far this has been borne out in rigorous work on important examples [32, 33, 54, 65, 72]. It is, in fact, the theory of extended TQFTs that provides the best information about the relationship between higher-dimensional algebra and TQFTs.

We could at this point attempt to define ‘manifolds with corners’ more precisely, and define composition operations on them. Various approaches have already been successfully pursued in the work mentioned above. However, in order to get an idea of what a convenient formalism should eventually look like, we prefer to turn to the theory of n -categories, and see what that suggests.

Strict n -Categories

Often when people refer to n -categories they mean what we shall call ‘strict’ n -categories. These appear not to be sufficiently general for TQFT applications, but unlike the more general ‘weak’ n -categories, they have already been defined for all n . In what follows we briefly sketch this definition and some of its implications, while in the next section we indicate the importance of weakening it in certain ways. Readers familiar with strict n -categories can skip this section. In the rest of this section we omit the qualifier ‘strict’.

The most elegant approach involves the theory of ‘enriched’ categories [47]. This is based on the observation that in the definition of a category C , the category Set , whose objects are sets and whose morphisms are functions, plays a distinguished role. The reason is that:

For every pair of objects x, y in C there is a *set* $\text{hom}(x, y)$ of morphisms, and for every triple of objects x, y, z in C composition is a *function* $\circ: \text{hom}(x, y) \times \text{hom}(y, z) \rightarrow \text{hom}(x, z)$.

Note also that the monoidal structure of Set , the Cartesian product \times , plays a role here. All the rest of the category axioms can be written out as commutative diagrams in the category Set , and all of these diagrams make sense in any monoidal category. Thus one can relativize the definition of a category by letting an arbitrary monoidal category K play the role that Set does here. In other words, a category C ‘enriched over K ’, or ‘ K -category’, is a collection of objects for which:

For every pair of objects x, y in C there is a *object* $\text{hom}(x, y)$ in K , and for every triple of objects x, y, z in C there is a *morphism* $\circ: \text{hom}(x, y) \otimes \text{hom}(y, z) \rightarrow \text{hom}(x, z)$ in K .

One also demands that the usual axioms of a category hold, translated into commutative diagrams in K .

A simple example is the category Vect , which is enriched over itself, or ‘closed’ [28]. That is, given vector spaces x and y , the set $\text{hom}(x, y)$ is actually a *vector space*, and composition $\circ: \text{hom}(x, y) \otimes \text{hom}(y, z) \rightarrow \text{hom}(x, z)$ is actually a *linear map*. Another example is the category of modules over a ring, which is enriched over the category of abelian groups.

This notion of enriched category permits a wonderful recursive definition of n -categories, as follows. We say a category is ‘small’ if the collection of objects is a set. The category of all small categories is denoted Cat — note that the ‘smallness’ condition prevents Russell-type paradoxes. Now Cat is actually a monoidal category, with the identity 1 taken as any category with one object x and one morphism 1_x , and with the tensor product being the usual Cartesian product \times of categories. This product is an obvious generalization of the Cartesian product of sets, as shown in Figure 13.

13. The Cartesian product of sets S and T , and of categories C and D

To be precise, the objects of $C \times D$, written as $x \times y$, are just ordered pairs consisting of an object x of C and an object y of D . The morphisms of $C \times D$ can be described using generators and relations. Given a morphism $f: x \rightarrow x'$ in C and a morphism $g: y \rightarrow y'$ in D , there are morphisms

$$x \times g: x \times y \rightarrow x \times y', \quad f \times y: x \times y \rightarrow x' \times y$$

in $C \times D$. These are the generators; the relations say that

$$(f \times y)(f' \times y) = ff' \times y, \quad (x \times g)(x \times g') = x \times gg',$$

and very importantly, that diagrams of the following form commute:

$$\begin{array}{ccc}
 x \times y & \xrightarrow{f \times y} & x' \times y \\
 \downarrow x \times g & & \downarrow x' \times g \\
 x \times y' & \xrightarrow{f \times y'} & x' \times y'.
 \end{array} \tag{2}$$

This implies that all the squares in Figure 13 commute.

The definition of (strict) n -categories is then as follows. 2-categories are simply categories enriched over Cat . The category 2Cat of small 2-categories, in turn, has a Cartesian product making it into a monoidal category. This allows us to define 3-categories as categories enriched over 2Cat . In general, $n\text{Cat}$ is defined as the category of small categories enriched over $(n-1)\text{Cat}$, which is monoidal when equipped with its Cartesian product. The Cartesian product at each stage is defined by a generalization of the Cartesian product of categories to the enriched context [47].

For the reader dizzied by the rapid ascent up this recursive ladder, let us briefly pause to contemplate the case of 2-categories [49]. Here for any pair of objects x and y , $\text{hom}(x, y)$ is a *category*. Objects in $\text{hom}(x, y)$ should be thought of as morphisms from x to y , while the morphisms in $\text{hom}(x, y)$ should be thought of as ‘morphisms between morphisms’ or 2-morphisms. The 2-morphisms are sometimes drawn as 2-dimensional surfaces labelled with double arrows; in Figure 14 we show objects x, y , morphisms $f: x \rightarrow y$ and $g: x \rightarrow y$, and a 2-morphism $\alpha: f \Rightarrow g$.

14. Diagram of a 2-morphism $\alpha: f \Rightarrow g$

Given objects x, y in a 2-category C and morphisms $f, g, h: x \rightarrow y$, we can compose 2-morphisms $\alpha: g \Rightarrow h$ and $\beta: f \Rightarrow g$ to obtain a 2-morphism $\alpha\beta: f \Rightarrow h$. This operation, which is really just composition of morphisms in the category $\text{hom}(x, y)$, is often called ‘vertical’ composition, for reasons made clear by Figure 15.

15. Vertical composition of 2-morphisms

On the other hand, given objects x, y and z , the composition functor from $\text{hom}(x, y) \times \text{hom}(y, z)$ to $\text{hom}(x, z)$, gives various other operations. Referring back to the definition of the Cartesian product of categories, one sees that composition takes an object in $\text{hom}(x, y)$ and one in $\text{hom}(y, z)$ to one in $\text{hom}(x, z)$: this is how one composes 1-morphisms in C . Composition also takes an object in one of these categories and a morphism in the other to a morphism in $\text{hom}(x, z)$. This gives two ways to compose a 1-morphism and a 2-morphism in C to obtain a 2-morphism, as shown in Figure 16.

16. Composition of a 1-morphism and a 2-morphism

Thanks to eq. (2), we can use these basic composition operations to define an operation called ‘horizontal composition’ of 2-morphisms, as shown in Figure 17. Given $f, f': x \rightarrow y$, $g, g': y \rightarrow z$, $\alpha: f \Rightarrow f'$ and $\beta: g \Rightarrow g'$, the horizontal composite of α and β is a 2-morphism $\alpha \otimes \beta: gf \Rightarrow g'f'$.

17. Horizontal composition of 2-morphisms

One can show that vertical and horizontal composition satisfy an ‘exchange identity’

$$(\alpha\alpha') \otimes (\beta\beta') = (\alpha \otimes \beta)(\alpha' \otimes \beta') \quad (3)$$

making the diagram in Figure 18 define a unique 2-morphism. This makes it quite convenient to define 2-morphisms diagrammatically by ‘pasting’ together diagrams, in a manner nicely mimicking how one can paste together 2-manifolds with corners. This is the basic sense in which 2-categories encode 2-dimensional topology.

18. Exchange identity

Just as the primordial example of a category is Set , the primordial example of a 2-category is Cat . We have already discussed Cat as a category in which the objects are small categories and the morphisms are functors. Actually, however, Cat is a 2-category, in which given functors $F, G: C \rightarrow D$, the 2-morphisms from F to G are the ‘natural transformations’ $\alpha: F \Rightarrow G$. Recall that such a thing assigns to each object x of C a morphism $\alpha_x: F(x) \rightarrow G(x)$, in such a way that for any morphism $f: x \rightarrow y$ in C , the consistency condition

$$\begin{array}{ccc} F(x) & \xrightarrow{\alpha_x} & G(x) \\ F(f) \downarrow & & \downarrow G(f) \\ F(y) & \xrightarrow{\alpha_y} & G(y) \end{array} \quad (4)$$

holds.

While this example may seem abstract, it has a certain inherently geometrical character. A functor $F: C \rightarrow D$ can be viewed as a diagram in D shaped liked C , and a natural transformation $\alpha: F \Rightarrow G$ should then be viewed as a prism in D going between two such diagrams, as shown in Figure 19.

19. Natural transformation α between functors $F, G: C \rightarrow D$

The consistency condition in the definition of a natural transformation says that the rectangular ‘vertical’ faces of this prism commute.

These remarks about 2-categories generalize considerably. In an n -category one has composition operations that allow one to paste together n -morphisms according to a wide variety of ‘pasting schemes’, much as one can glue together n -manifolds with corners [42]. Moreover, the primordial example of an $(n + 1)$ -category is $n\text{Cat}$. The reason is simply that $n\text{Cat}$ is closed, i.e., enriched over itself. That is, in addition to ‘ n -functors’ between n -categories and ‘ n -natural transformations’ between these, there are higher transformations between these which can be visualized using higher-dimensional analogs of Figure 19. Given two n -categories C and D , we thus obtain an n -category $\text{hom}(C, D)$.

Weakening

One profound difference between a set and a category is that elements of a set are either *equal* or not, while objects in a category can also be *isomorphic* in different ways (or not at all). Modern mathematics and physics takes advantage of this insight in many ways. For example, the fact that an object can admit nontrivial automorphisms is precisely what yields the notion of symmetry group. However, it is primarily category theorists who have followed through on this insight with the philosophy of ‘weakening’. As clearly enunciated by Kapranov and Voevodsky [46], this is based on the principle that “*In any category it is unnatural and undesirable to speak about equality of two objects.*” Instead, it is better whenever possible to speak in terms of isomorphisms between them.

For example, in the context of set theory, algebraic structures are frequently defined using equations. These structures can often be generalized to the context of category theory, but one has the choice of generalizing them ‘strictly’ — keeping the equations as equations — or ‘weakly’ — replacing the equations by specified isomorphisms. When one opts to ‘weaken’ a definition in this way, one typically demands that the isomorphisms themselves satisfy new equations, called ‘coherence laws’, in order to manipulate them with some of the same facility as the original equations. For example, a monoid is a set with a product that is required among other things to

satisfy the equation $(xy)z = x(yz)$. The categorical analog of a monoid is a category with tensor product, or monoidal category. Actually, though, monoidal categories come in two versions: strict, where the associativity of the tensor product is given by an equation:

$$(x \otimes y) \otimes z = x \otimes (y \otimes z),$$

and ‘weak’, where instead there is a natural isomorphism, the ‘associator’:

$$A_{x,y,z}: (x \otimes y) \otimes z \rightarrow x \otimes (y \otimes z).$$

The associator allows one to rebracket iterated tensor products, but to make sure that any two different paths of rebracketings have the same effect one must impose the ‘pentagon identity’, that

$$\begin{array}{ccc}
 ((x \otimes y) \otimes z) \otimes w & \xrightarrow{A_{x \otimes y, z, w}} & (x \otimes y) \otimes (z \otimes w) \xrightarrow{A_{x, y, z \otimes w}} x \otimes (y \otimes (z \otimes w)) \\
 \downarrow A_{x, y, z} \otimes 1_w & & \uparrow 1_x \otimes A_{y, z, w} \\
 (x \otimes (y \otimes z)) \otimes w & \xrightarrow{A_{x, y \otimes z, w}} & x \otimes ((y \otimes z) \otimes w)
 \end{array}$$

commutes. Similarly, in a weak monoidal category the equations $1x = x1 = x$ holding in a monoid are replaced by isomorphisms satisfying coherence laws.

The monoidal categories that arise in nature, such as $n\text{Cob}$ and Vect , are usually weak. People frequently ignore this fact, however (and the reader will note we did so in Section 1). The justification for doing so is Mac Lane’s theorem [56] that any weak monoidal category is equivalent to a strict one. However, the sense of ‘equivalence’ here is rather subtle and itself intimately connected with weakening. Following Kapranov and Voevodsky’s principle, in addition to weakening algebraic structures, one should also weaken the sense in which maps between them preserve the structure. For example, the strictest notion of a ‘monoidal functor’ between monoidal categories would require that it preserve tensor products ‘on the nose’. A weaker and often more useful notion, however, requires merely that it preserve tensor products *up to a natural isomorphism* compatible with the associativity constraints. It is this weaker notion which plays a role in the definition of ‘equivalence’ of monoidal categories.

Mac Lane’s theorem is an example of the ‘strictification’ theorems in higher-dimensional algebra. These assert that any weakened algebraic structure of a given sort is equivalent to some stricter counterpart, in an appropriately weakened sense of ‘equivalence’. They simplify certain computations by allowing us to consider a special class of cases without essential loss of generality.

However, in many situations weak notions are more general than their strict counterparts in interesting ways. Also, there is a certain matter of choice involved in

picking coherence laws, and this can lead to different degrees of weakening. For example, one weakened categorical analog of a commutative monoid is a symmetric monoidal category, the equation $xy = yx$ having been replaced by an isomorphism $B_{x,y}: x \otimes y \rightarrow y \otimes x$ satisfying various coherence laws including $B_{y,x}B_{x,y} = 1_{x \otimes y}$. The stricter notion where commutativity remains an equation is too narrow to be very interesting. However, a still weaker notion *is* very interesting, namely a ‘braided’ monoidal category, in which the coherence law $B_{y,x}B_{x,y} = 1_{x \otimes y}$ is dropped.

As the name suggests, braided monoidal categories are important in 3-dimensional topology [20, 34, 66]. A further ‘categorification’ of the notion of commutative monoid, namely a braided monoidal 2-category, appears to play a corresponding role in 4-dimensional topology [18, 46]. One goal of the n -categorical approach to TQFTs is to systematically understand why weakened categorical analogs of familiar algebraic structures are important in topology.

Perhaps the most fundamental candidate for weakening is the definition of n -category itself. In the context of n -categories, Kapranov and Voevodsky’s principle indicates that it is undesirable to speak of equality between two k -morphisms when $k < n$; instead, one should speak in terms of $(k + 1)$ -isomorphisms between them. One can unfold the recursive definition of strict n -category and obtain a completely ‘explicit’ definition in terms of operations on k -morphisms, which are required to satisfy various equations. Each equation presents an opportunity for repeated weakening. For example, we can weaken an equation between k -morphisms by replacing it with a natural $(k + 1)$ -isomorphism and demanding that this new isomorphism satisfy coherence laws. We can weaken further by replacing these coherence laws with $(k + 2)$ -isomorphisms, which must satisfy their own coherence laws, and so on. This process becomes increasingly complex with increasing n , and so far the definition of what might be called a ‘weak n -category’ has only been worked out for $n \leq 3$.

In defining n -categories with $n = 0$ or 1 — i.e., in defining sets or categories — there is no opportunity for weakening. Weak 2-categories are usually known as ‘bicategories’ [12], but there is a strictification theorem saying that all of these are equivalent (or more precisely, biequivalent) to strict 2-categories. Weak 3-categories, or ‘tricategories’, have recently been developed by Gordon, Power, and Street [37]. These are *not* all triequivalent to strict 3-categories, but there *is* a strictification theorem saying they are triequivalent to ‘semistrict 3-categories’. These are categories enriched over 2Cat thought of as a monoidal category not with its Cartesian product, but with a weakened product similar to that defined by Gray [38]. In this ‘semistrict’ tensor product, eq. (2) is dropped, and instead there is only a natural 2-isomorphism between the left- and right-hand sides. Topologically this is very natural, since it means that the squares in Figure 20, rather than commuting, are ‘filled in’ with 2-isomorphisms.

20. The semistrict tensor product of 2-categories

To advance further in n -category theory, it is urgent to define ‘weak n -categories’ for all n . It is clear that new ideas are needed to do so without a combinatorial explosion, since already the explicit definition of a tricategory takes 6 pages, and that of a triequivalence 13 pages! However, the potential payoffs of a good theory of weak n -categories should encourage us to persevere.

Having completed our brief survey of n -category theory, let us return to topological quantum field theory. In what follows, we propose answers to the basic questions: *Of which n -category are n -dimensional extended TQFTs representations?* and *In what sense is an n -dimensional extended TQFT a representation of this n -category?* Our answers are inevitably somewhat vague, except for low n , since they rely on notions from the theory of weak n -categories. Nonetheless, we hope they will serve as a guide for future research.

Suspension

To begin, it is useful to consider an issue that might at first seem of purely formal interest. Suppose we have an $(n + 1)$ -category C with only one object x . We can regard C as an n -category \tilde{C} by re-indexing: the objects of \tilde{C} are the morphisms of C , the morphisms of \tilde{C} are the 2-morphisms of C , and so on. However, the n -categories we obtain this way will have extra structure. For example, since the objects of \tilde{C} were really morphisms in C from x to itself, we can multiply (i.e., compose) them. We have already seen the simplest example of this phenomenon in Section 1: if C is a category with a single object, \tilde{C} is a monoid. If instead we start with a strict (resp. weak) 2-category with a single object, we obtain a strict (resp. weak) monoidal category! Similarly, starting with strict, semistrict, or weak 3-categories with only one object, we obtain corresponding sorts of monoidal 2-categories, i.e., 2-categories having tensor products of objects, morphisms, and 2-morphisms [37, 46].

We can iterate this process, and construct from an $(n + k)$ -category C with only one object, one morphism, and so on up to one $(k - 1)$ -morphism, an n -category \tilde{C} whose j -morphisms are the $(j + k)$ -morphisms of C . In doing so we obtain a particular sort of n -category with extra structure and properties, which we call a

‘ k -tuply monoidal’ n -category. In Figure 21 we tabulate our best guesses concerning k -tuply monoidal n -categories. Ultimately we expect a table along these lines for *weak* k -tuply monoidal n -categories. For the moment, however, we work with ‘semistrict’ ones, which have already been defined in a few cases where the weak ones have not. The idea is that strictification theorems are either known or expected saying that all weak k -tuply monoidal n -categories are equivalent (in a suitable sense) to these semistrict ones.

More precisely, for the $n = 0$ and $n = 1$ columns we define the semistrict notions to be the same as the strict ones. In the $n = 2$ column, we define semistrict 2-categories to be strict ones, while semistrict monoidal and braided monoidal 2-categories have been defined by Kapranov and Voevodsky [46]. Semistrict weakly and strongly involutory monoidal 2-categories have been discussed by Breen [14]. Semistrict 3-categories, mentioned in the previous section, have been studied by Gordon, Power and Street [37] and Leroy [55].

	$n = 0$	$n = 1$	$n = 2$
$k = 0$	sets	categories	2-categories
$k = 1$	monoids	monoidal categories	monoidal 2-categories
$k = 2$	commutative monoids	braided monoidal categories	braided monoidal 2-categories
$k = 3$	‘	symmetric monoidal categories	weakly involutory monoidal 2-categories
$k = 4$	‘	‘	strongly involutory monoidal 2-categories
$k = 5$	‘	‘	‘

21. Semistrict k -tuply monoidal n -categories

There are many interesting patterns to be seen in this table. First, it is clear that many of the concepts already discussed appear in this table, together with some new ones. Second, as we proceed down any column of this table, the n -categories in question first gain additional structures, which then acquire additional properties of an ‘abelian’ nature. This process appears in its most rudimentary form in the first column. We have already seen that a category with only one object x is essentially the same as the monoid $\text{hom}(x, x)$. Why does a 2-category C with only one object x and one morphism 1_x give a *commutative* monoid $\text{hom}(1_x, 1_x)$?

The argument goes back at least to Eckmann and Hilton [27]. The elements of $\text{hom}(1_x, 1_x)$ are the 2-morphisms of C , and as described in our brief review of 2-

categories, we can compose $\alpha, \beta: 1_x \Rightarrow 1_x$ either vertically or horizontally to obtain a new 2-morphism from 1_x to 1_x . We write the vertical composite as $\alpha\beta$ and the horizontal composite as $\alpha \otimes \beta$. Writing simply 1 for 1_{1_x} , with a little work one can check that $1 \otimes \alpha = \alpha \otimes 1 = \alpha$, so that 1 is the identity for both vertical and horizontal composition. One also has the exchange identity $(\alpha\alpha') \otimes (\beta\beta') = (\alpha \otimes \beta)(\alpha' \otimes \beta')$ from eq. (3). These two facts let us perform the remarkable computation:

$$\begin{aligned}
\alpha \otimes \beta &= (1\alpha) \otimes (\beta 1) & (5) \\
&= (1 \otimes \beta)(\alpha \otimes 1) \\
&= \beta\alpha \\
&= (\beta \otimes 1)(1 \otimes \alpha) \\
&= (\beta 1) \otimes (1\alpha) \\
&= \beta \otimes \alpha,
\end{aligned}$$

so vertical and horizontal composition are equal and $\text{hom}(1_x, 1_x)$ is a commutative monoid. Conversely, one can show that any commutative monoid can be thought of as the 2-morphisms in a 2-category with one object and one morphism.

When we consider a semistrict 3-category with one object x , one morphism 1_x , and one 2-morphism 1_{1_x} , it turns out that these are again essentially just commutative monoids. The same appears to be true for semistrict 4-categories with only one 3-morphism. While semistrict 4-categories are not understood in general, it seems that those with only one morphism are, these being braided monoidal 2-categories, and one can check that of these, those with only one 3-morphism are commutative monoids. Of course this argument is somewhat circular, since it assumes we understand one column of the table in order to check another, but it serves as an interesting cross-check. In any event, it appears that the $n = 0$ column *stabilizes* after two steps.

The same sort of process is at work in the next two columns, in increasingly sophisticated incarnations. The basic pattern is shown in Figure 22.

	$n = 0$	$n = 1$	$n = 2$
$k = 0$	sets	categories	2-categories
$k = 1$	xy	$x \otimes y$	$x \otimes y$
$k = 2$	$xy = yx$	$B_{x,y}: x \otimes y \rightarrow y \otimes x$	$B_{x,y}: x \otimes y \rightarrow y \otimes x$
$k = 3$	‘	$B_{x,y} = B_{y,x}^{-1}$	$I_{x,y}: B_{x,y} \Rightarrow B_{y,x}^{-1}$
$k = 4$	‘	‘	$I_{x,y} = (I_{y,x}^{-1})_{hor}^{-1}$

22. Semistrict k -tuply monoidal n -categories: structure and properties

In the $n = 0$ column we began with sets, which then acquired a product, which then satisfied the commutativity equation $xy = yx$. In the $n = 1$ we begin with categories, which permit a more nuanced version of the process: first they acquire a product, then they acquire an isomorphism $B_{x,y}: x \otimes y \rightarrow y \otimes x$, taking the place of the commutativity

equation. Finally, the braiding is required to satisfy an equation of its own, the symmetry equation $B_{x,y} = B_{y,x}^{-1}$. Note that what was a property (commutativity) has become structure (the braiding), which then acquires an analogous property of its own (symmetry).

In the $n = 2$ column a still more subtle version of the ‘abelianization’ process occurs. We begin with 2-categories. These first acquire a product, then a braiding isomorphism, and then a 2-isomorphism $I_{x,y}: B_{x,y} \Rightarrow B_{y,x}^{-1}$, the ‘involutor’, taking the place of the symmetry equation. In the last step, the involutor satisfies an equation of its own, $I_{x,y} = (I_{y,x}^{-1})^{-1}$, meaning that the horizontal composite of $I_{x,y}$ and $I_{y,x}^{-1}$ is the identity. One can also think of both sides of the equation as 2-isomorphisms from $B_{x,y}$ to $B_{y,x}^{-1}$. We give a topological interpretation of this equation in Section 7.

The pattern here is evident, at least in outline, and it is tempting to predict that it continues for higher n . In particular, we can guess that each column will take one step longer to stabilize. A bit more precisely, let $n\text{Cat}_k$ denote the category of k -tuply monoidal weak n -categories. There should be a forgetful functor

$$F: n\text{Cat}_k \rightarrow n\text{Cat}_{k-1},$$

and a corresponding ‘reverse’ functor, technically a left adjoint

$$S: n\text{Cat}_{k-1} \rightarrow n\text{Cat}_k,$$

which we shall call ‘suspension’ (for reasons to become clear shortly). For example, when we repeatedly suspend a set C , we obtain first the free monoid on C , and then the abelianization thereof. Similarly, when we repeatedly suspend a category C , we obtain first the free monoidal category on C , then the free braided monoidal category on C , and then the symmetrization thereof. We propose the:

Stabilization Hypothesis. *After suspending a weak n -category $n + 2$ times, further suspensions have no essential effect. More precisely, the suspension functor $S: n\text{Cat}_k \rightarrow n\text{Cat}_{k+1}$ is an equivalence of categories for $k \geq n + 2$.*

We could also embellish this hypothesis by considering $n\text{Cat}_k$ not merely as a category but as $(n + k + 1)$ -category, and using not equivalence but some notion of ‘ $(n + k + 1)$ -equivalence’.

One can regard the above hypothesis, and those to follow, either as a conjecture pending a general definition of ‘weak n -category’, or as a feature one might desire of such a definition. Apart from the already given algebraic evidence for the stabilization hypothesis, there is quite a bit of indirect topological evidence from homotopy theory and the theory of tangles. The latter leads us back to our goal: understanding topological quantum field theory in n -categorical terms.

Homotopy Theory

Modern higher-dimensional algebra has its roots in the dream of finding a natural and convenient *completely algebraic* description of the homotopy type of a topological space. The prototype here is the fundamental groupoid; given a space X , this is the category $\Pi_1(X)$ whose objects are the points of X and whose morphisms are the homotopy classes of paths (with fixed endpoints). This is a groupoid, meaning that every morphism has an inverse, given by reversing a path from x to y to obtain a path from y to x . In fact, Π_1 gives an equivalence between the category of groupoids and the category of ‘homotopy 1-types’, where, roughly speaking, two spaces define the same homotopy n -type if they are equivalent as far as concerns homotopy classes of maps from n -dimensional CW complexes into them.

The goal of generalizing the fundamental groupoid to higher dimensions has led to a variety of schemes. One of the most popular involves Kan complexes [60], which model a space by an algebraic analog of a simplicial complex. Alternative approaches based on cubes have been developed by Brown, Higgins, Loday and others [16]. Indeed, it was in this context that Brown first coined the term ‘higher-dimensional algebra’.

Here, however, we restrict our attention to n -categorical approaches. Ever since Grothendieck’s famous 600-page letter to Quillen [39], it has been tempting to associate to a space X a ‘fundamental n -groupoid’ $\Pi_n(X)$, some sort of n -category whose objects are points, whose morphisms are paths, whose 2-morphisms are paths between paths, and so on up to the n -morphisms, which are homotopy classes of n -fold paths. This amounts to taking the imagery of n -category theory quite literally, as in Figure 23, where we show a typical 2-morphism.

23. A 2-morphism in the fundamental n -groupoid

Roughly speaking, an n -groupoid should be some sort of n -category in which all k -morphisms ($k \geq 1$) have inverses, at least weakly. There are good reasons to want to use weak n -categories here. In the fundamental groupoid, composition is associative, since the morphisms are merely homotopy classes of paths. In the fundamental 2-groupoid, however, composition of paths $f: [0, 1] \rightarrow X$ is not strictly associative, but only up to a homotopy, the associator, which performs the reparametrization of $[0, 1]$ shown in Figure 24.

24. The associator in homotopy theory

In the fundamental 2-groupoid, the associator satisfies the pentagon identity ‘on the nose’, but in higher fundamental n -groupoids it does so only up to a homotopy, which in turn satisfies a coherence condition up to homotopy, and so on. In fact, the whole tower of these ‘higher associativity laws’ was worked out by Stasheff [69] in 1963, and have an appealing geometrical description as faces of the ‘associahedron’. For example, the pentagon, being a 2-morphism, is a 2-dimensional face. One expects these higher associativity laws to play a crucial part in the definition of weak n -categories, as indeed they do in the cases understood so far ($n \leq 3$). Similar remarks hold for the identity law [37] and for the inverses.

Of course, one expects strictification theorems saying that ‘weak n -groupoids’ are all ‘ n -equivalent’ to some better-behaved class of n -groupoids, implying that the latter are sufficient for homotopy theory. There are, in fact, two distinct strands of progress along these lines. First, the category of homotopy 2-types has been shown equivalent to a category whose objects are strict 2-categories having strict inverses for all k -morphisms [17, 58]. Moreover, the category of homotopy 3-types has been shown equivalent to a category whose objects are semistrict 3-categories having strict inverses [44, 55]. This naturally suggests the possibility that homotopy n -types might be equivalent to some sort of semistrict n -categories having strict inverses. Second, for all n the category of homotopy n -types has been shown equivalent to a category whose objects are strict n -categories having a particular sort of ‘weak inverses’ [45]. We see here a kind of tradeoff that would be nice to understand better.

In any event, while the correspondence between homotopy n -types and ‘weak n -groupoids’ is still incompletely understood, it is already very valuable, since it sets up an analogy between topological spaces and n -categories that lets us import techniques and insights from topology into higher-dimensional algebra. In what follows we use this analogy to shed some light on the stabilization hypothesis of the previous section.

First, the topologically minded reader might already have noticed that the $n = 0$ column of Figure 21 — sets, monoids, and commutative monoids thereafter — is familiar from homotopy theory. Typically in homotopy theory one works with spaces with basepoint, and defines $\pi_k(X)$ to be the set of homotopy classes of based maps from S^n to X . For $k = 0$, $\pi_k(X)$ is indeed just a set, while for $k = 1$ it is a group, and for $k \geq 2$ it is an abelian group. These facts can be seen as *consequences* of Figure 21 together with the correspondence between homotopy n -types and weak n -groupoids, but historically, of course, they were discovered first.

In particular, the Eckmann-Hilton argument given in eq. (5) is just the algebraic

distillation of a very topological proof that π_2 is abelian. We illustrate the key steps of eq. (5) in Figure 25. Here each rectangle is labelled with a map from the rectangle to some space X , mapping the boundary to the basepoint of X . Such a map can be thought of as a based map from S^2 to X , defining an element of $\pi_2(X)$. In Figure 25, α and β represent arbitrary based maps from S^2 to X , while 1 represents the trivial map sending all of S^2 to the basepoint of X . Such maps can be either vertically or horizontally composed by juxtaposition. and the figure shows successive frames in a movie of a homotopy from $\alpha \otimes \beta$ to $\beta \otimes \alpha$, proving that $\pi_2(X)$ is abelian. The same sort of argument shows that $\pi_k(X)$ is abelian for all $k \geq 2$.

25. The Eckmann-Hilton argument

Figure 25 also clarifies how, when we proceed from the $n = 0$ to the $n = 1$ column in Figure 21, the commutativity equation is weakened to a braiding isomorphism. In $\pi_2(X)$, homotopic maps from S^2 to X are decreed to be *equal*. In a more refined context, however, we could regard the homotopy as an *isomorphism*. In Figure 26 we depict the homotopy from $\alpha \otimes \beta$ to $\beta \otimes \alpha$ given by the Eckmann-Hilton argument as a map from the cube to X , whose horizontal slices give the frames of the movie shown in Figure 25. (Here we have compressed α and β to small discs for clarity; everything outside these discs is mapped to the basepoint of X .) One can see that this homotopy is precisely a braiding!

26. Braiding $B_{\alpha,\beta}: \alpha \otimes \beta \rightarrow \beta \otimes \alpha$

In particular, an alternate version of the Eckmann-Hilton argument:

$$\begin{aligned}
\alpha \otimes \beta &= (\alpha 1) \otimes (1\beta) \\
&= (\alpha \otimes 1)(1 \otimes \beta) \\
&= \alpha\beta \\
&= (1 \otimes \alpha)(\beta \otimes 1) \\
&= (1\beta) \otimes (\alpha 1) \\
&= \beta \otimes \alpha,
\end{aligned}$$

gives another homotopy from $\alpha \otimes \beta$ to $\beta \otimes \alpha$, corresponding to $B_{\beta,\alpha}^{-1}$, as shown in Figure 27.

$$27. B_{\beta,\alpha}^{-1}: \alpha \otimes \beta \rightarrow \beta \otimes \alpha$$

These two homotopies are not generally homotopic to each other, corresponding to the fact that generally $B_{\alpha,\beta} \neq B_{\beta,\alpha}^{-1}$ in a braided monoidal category. This is a good example of how different *proofs* of the same equation may, upon weakening, give rise to distinct isomorphisms.

Algebraically, the point here is that the Eckmann-Hilton argument relies on the interplay between horizontal and vertical composition of 2-morphisms in 2-categories. For the definition of horizontal composition given in Figure 17 to be unambiguous, we needed the commuting square condition, eq. (2), in the definition of the Cartesian product of categories. In the context of semistrict 3-categories this equation is weakened to an isomorphism, as shown in Figure 20, so Figure 17 gives two distinct notions of horizontal composition of 2-morphisms, related by a 3-isomorphism. Arbitrarily picking one of these, and recapitulating the Eckmann-Hilton argument in this context, one finds that instead of an equation between $\alpha \otimes \beta$ and $\beta \otimes \alpha$, one has a 3-isomorphism, the braiding.

Lest the reader think we have drifted hopelessly far from physics by now, we should note that elements of $\pi_2(X)$ correspond to ‘topological solitons’ in a nonlinear sigma model with target space X , for a spacetime of dimension 3. In this context, Figures 26 and 27 show the worldlines of such topological solitons, and the fact that the two pictures cannot be deformed into each other is why the statistics of such solitons is described using representations of the braid group [8]. In a spacetime of dimension 4

or more, the analogous pictures *can* be deformed into each other, since there is enough room to pass the two strands across each other. Topologically, this means that the two homotopies from $\alpha \otimes \beta$ to $\beta \otimes \alpha$ are themselves homotopic when α, β represent based maps from S^k to X for $k \geq 3$. Algebraically, this corresponds to moving down in Figure 21 from braided monoidal categories to symmetric monoidal categories, where one has $B_{\alpha, \beta} = B_{\beta, \alpha}^{-1}$. Physically, this is why the statistics of topological solitons in spacetimes of dimension 4 or more is described using the symmetric group.

Having discussed the $n = 0$ and $n = 1$ columns of Figure 21 from the viewpoint of homotopy theory, we could proceed to the $n = 2$ column, but instead let us explain the general pattern and what it has to do with the stabilization hypothesis. In fact, the ‘suspension’ operation on n -categories is closely modelled after homotopy theory. In topology, one obtains the ‘suspension’ SX of a space X with basepoint $*$ as a quotient space of $X \times [0, 1]$ in which one collapses all the points of the form $(x, 0)$, $(x, 1)$, and $(*, t)$ to a single point. We can draw this as in Figure 28, with the proviso that all the points on the dotted line are identified.

28. Space X and its suspension SX

In fact, suspension is a functor, so a map $f: X \rightarrow Y$ gives rise to a map $Sf: SX \rightarrow SY$, and one obtains thereby a sequence

$$[X, Y] \xrightarrow{S} [SX, SY] \xrightarrow{S} [S^2X, S^2Y] \xrightarrow{S} \dots$$

where $[X, Y]$ denotes the set of homotopy classes of maps from X to Y . Moreover, if X is a CW complex of dimension n , this sequence stabilizes after $n + 2$ steps, i.e., the map

$$S: [S^k X, S^k Y] \rightarrow [S^{k+1} X, S^{k+1} Y]$$

is an isomorphism for $k \geq n + 2$. This theorem is the basis of stable homotopy theory, a subject with close ties to higher-dimensional algebra [1]. Given the conjectured relation between homotopy n -types and weak n -groupoids, one expects this theorem to translate into a proof of our stabilization hypothesis in the special case of weak n -groupoids. Roughly speaking, the idea is that when we suspend X , a k -morphism in the fundamental n -groupoid of X gives a $(k + 1)$ -morphism in the fundamental $(n + 1)$ -groupoid of SX in a manner analogous to the algebraic notion of suspension described in Section 5. In Figure 29, for example, we show how a point of X gives a loop in SX , and how a path in X gives a path between loops in SX .

29. Suspending k -morphisms in the fundamental n -groupoid of a space X

For readers comfortable with homotopy theory we can make this a bit more precise as follows. Let $n\text{Hot}_k$ denote the category of pointed $(k-1)$ -connected homotopy $n+k$ -types for $k \geq 1$, or just homotopy n -types for $k = 0$. Then we can think of suspension as a functor $\tilde{S}: n\text{Hot}_k \rightarrow n\text{Hot}_{k+1}$, where we take the reduced suspension for $k \geq 1$, while for $k = 0$ we first adjoin a basepoint and then take the reduced suspension. Now suppose we have an equivalence $\Pi: n\text{Hot}_k \rightarrow n\text{Gpd}_k$ to some category of weak n -groupoids, with adjoint given by a functor $N: n\text{Gpd} \rightarrow n\text{Hot}$, where N is obtained by composing a kind of ‘nerve’ functor with ‘geometrical realization’. One expects that the n -categorical suspension functor of the previous section yields one for weak n -groupoids, say $S: n\text{Gpd}_k \rightarrow n\text{Gpd}_{k+1}$, where $n\text{Gpd}_k$ denotes the category of k -tuply monoidal weak n -groupoids, and that S is equivalent to $N\tilde{S}\Pi$. If this is so, the stabilization result from homotopy theory should imply that S is an equivalence for $k \geq n + 2$. This argument also makes it clear that the forgetful functor from $n\text{Cat}_k$ to $n\text{Cat}_{k-1}$ is analogous to *looping* in homotopy theory [46].

Tangles

Now let us venture an answer to the question: *Of which n -category are n -dimensional extended TQFTs representations?* Recall from Section 2 that we expect this to be an n -category in which the objects are 0-manifolds, the morphisms are 1-manifolds with boundary, the 2-morphisms are 2-manifolds with corners, and so on. These should all be oriented, but experience with 3-dimensional TQFTs has shown that it may be convenient to equip them with some extra structure as well, a kind of ‘framing’. One could attempt to make this more precise and give an explicit description of the resulting n -category in terms of generators and relations. Instead, we try to isolate the crucial algebraic properties of this n -category, and hypothesize that it is in fact the universal n -category with these properties. We have already seen that a key feature of the n -categories appropriate for homotopy theory is the presence of *inverses*. Here we wish to argue that the corresponding feature of the n -category of which extended TQFTs are representations is the presence of *duals*. Of course, both ‘inverses’ and ‘duals’ may need to be understood in an appropriately weakened sense.

We have already seen two levels of duality in the definition of a unitary TQFT. First, in $n\text{Cob}$ each object x is an oriented $(n - 1)$ -manifold, and its dual x^* is the same manifold with its orientation reversed. Second, each morphism $f: x \rightarrow y$ is an oriented n -manifold with boundary, and its dual $f^\dagger: y \rightarrow x$ is the same manifold with its orientation reversed. It is important to note that the dual morphism $f^\dagger: y \rightarrow x$ is different from the ‘adjoint’ morphism $f^*: y^* \rightarrow x^*$ given by the composite

$$y^* \xrightarrow{1 \otimes i_x} y^* \otimes x \otimes x^* \xrightarrow{1 \otimes f \otimes 1} y^* \otimes y \otimes x^* \xrightarrow{e_y \otimes 1} x^*.$$

The notion of adjoint morphism is derived from duality on objects, but the notion of dual morphism is conceptually independent. Presumably this is just the tip of the iceberg: in the n -categorical formulation of the theory of cobordisms there should be $n + 1$ distinct levels of duality, corresponding to orientation reversal for j -manifolds with corners for all $0 \leq j \leq n$.

Indeed, while the details have only been worked out in special cases, it seems that there should be a general notion of a k -tuply monoidal n -category ‘with duals’. Such a structure should have $n + 1$ duality operations, allowing us to take duals of j -morphisms for all $0 \leq j \leq n$. For the moment let us denote all these duality operations with the symbol $*$. For $j > 0$ the dual of a j -morphism $f: x \rightarrow y$ is a j -morphism $f^*: y \rightarrow x$, while the dual of a 0-morphism, or object, is simply another object. For all $0 < j < n$ there should be an associated unit and counit

$$i_f: 1_y \rightarrow f f^*, \quad e_f: f^* f \rightarrow 1_x,$$

satisfying the triangle identities, probably in a weakened sense. Note that for n -morphisms there cannot be a unit and counit since there are no $(n + 1)$ -morphisms. Also, there can only be a unit and counit for objects in the presence of a monoidal structure, that is, if $k \geq 1$. In this case, if we write the monoidal structure as a tensor product, the unit and counit for object take the usual forms as in eq. (1). Other properties we expect of duality are $f^{**} = f$, and $(fg)^* = g^* f^*$ whenever the j -morphisms f, g can be composed.

Since the precise axioms for a k -tuply monoidal n -category ‘with duals’ have only been formulated in certain semistrict cases, let us go through them one by one. We shall pay special attention to the example of the *free semistrict k -tuply monoidal n -category with duals on one object*. We denote this n -category by $C_{n,k}$ and the generating object by x . We hypothesize that the weak analog of this n -category has a special significance for topological quantum field theory:

Tangle Hypothesis. The n -category of framed n -tangles in $n + k$ dimensions is $(n + k)$ -equivalent to the free weak k -tuply monoidal n -category with duals on one object.

The sort of tangle studied in knot theory is what we would call a 1-tangle in 3 dimensions, shown in the $n = 1, k = 2$ entry of Figure 30 below. By an n -tangle in

$n + k$ dimensions we intend a generalization of this concept, roughly speaking an n -manifold with corners embedded in $[0, 1]^{n+k}$ so that the codimension j corners of the manifold are mapped into the subset of $[0, 1]^{n+k}$ for which the last j coordinates are either 0 or 1. By a ‘framing’ of an n -tangle we mean a homotopy class of trivializations

$n = 0$

$n = 1$

$n = 2$

$k = 0$

$k = 1$

$k = 2$

$k = 3$

$k = 4$

30. Examples of n -morphisms in $C_{n,k}$, drawn as n -tangles in $n + k$ dimensions

of the normal bundle. (Such a framing, together with the standard orientation on $[0, 1]^{n+k}$, determines an orientation on the submanifold.)

Implicit in the tangle hypothesis is that there should be a weak n -category whose n -morphisms are suitably defined isotopy classes of n -tangles in $n + k$ dimensions. The precise definition of ‘ n -tangles’ and ‘isotopy classes’ for this purpose is only well-understood for $n = 1$, and only beginning to be understood for $n = 2$. In what sense should isotopy classes of n -tangles in $n + k$ dimensions be the n -morphisms in an n -category? Roughly, a j -morphism $f: x \rightarrow y$ in this n -category should be a certain equivalence class of j -tangles in $[0, 1]^{j+k}$, going from the equivalence class x of $(j - 1)$ -tangles in $[0, 1]^{j+k-1} \times \{0\}$ to the equivalence class y of $(j - 1)$ -tangles in $[0, 1]^{j+k-1} \times \{1\}$. The duality operation on j -tangles corresponds to reflection of $[0, 1]^{j+k}$ about the last coordinate axis.

Clearly much remains to be made precise here. Rather than continuing to speak in generalities, let us describe what is known so far in various special cases. This should also be the best way of illustrating the significance of the k -tuply monoidal structure.

We begin with $n = 0$ column of Figure 30. Here there is just one level of duality to consider, which we denote by $*$. For $k = 0$, a k -tuply monoidal n -category C is just a set. A set ‘with duals’ is simply one equipped with an involution, that is, a function $*: C \rightarrow C$ with $x^{**} = x$ for all x . Thus $C_{0,0}$ is the free set with involution on one object x , namely the two-element set $\{x, x^*\}$. Now for $k > 0$, a framing of a 0-dimensional submanifold of $[0, 1]^k$ is equivalent to an orientation, so in this degenerate case we somewhat artificially identify a framing with an orientation. The cobordism hypothesis then states that $C_{0,0}$ describes the set of isotopy classes of oriented 0-tangles in 0 dimensions — i.e., the positively and negatively oriented point!

Proceeding down the column to $k = 1$, a k -tuply monoidal n -category C is just a monoid. A monoid ‘with duals’ is one equipped with an involution, which in this context means a function $*: C \rightarrow C$ with $x^{**} = x$ and $(xy)^* = y^*x^*$. Thus $C_{0,1}$ is the free monoid with involution on one object x . Elements of $C_{0,1}$ are thus formal (noncommuting) products of the elements x and x^* . These correspond to isotopy classes of oriented 0-tangles in $[0, 1]$, or simply strings of positively and negatively oriented points, as shown in Figure 30.

Continuing down to $k = 2$, a k -tuply monoidal n -category is a commutative monoid, and again ‘having duals’ simply means being equipped with an involution. Thus $C_{0,2}$ is the free commutative monoid on one object x . Any element of $C_{0,2}$ is thus of the form $x^n(x^*)^m$. Similarly, an isotopy class of oriented 0-tangles in 2 dimensions is just a collection of n positively oriented and m negatively oriented points. The same holds for all dimensions $k \geq 2$, essentially because there are enough dimensions to freely move the points about in a manner corresponding to the Eckmann-Hilton argument.

In the $n = 1$ column we have various kinds of category with extra structure. Here

there are two levels of duality — duality for objects and duals for morphisms — so to avoid confusion we denote the dual of an object x by x^* , and the dual of a morphism $f: x \rightarrow y$ by $f^\dagger: y \rightarrow x$. For $k = 0$ we just have categories, and by a category ‘with duals’ we mean one equipped with operations $*$ and \dagger as just described, such that $*^2 = 1$ on objects, $\dagger^2 = 1$ on morphisms, and $(fg)^\dagger = g^\dagger f^\dagger$. With this definition, $C_{1,0}$, the free category with duals on one object x , is rather dull: it has objects x and x^* and only identity morphisms. If we artificially take a framing in this degenerate case to mean an orientation, the tangle hypothesis states that the morphisms in this category correspond to isotopy classes of oriented 1-tangles in 1 dimension. There are indeed only two of these, one of which is shown in Figure 30.

Moving down the $n = 1$ column to $k = 1$, we have monoidal categories. This is the first point at which there is room for the unit and counit. By a monoidal category ‘with duals’ we thus mean a category with duals in the above sense which is also monoidal, for which $(x \otimes y)^* = y^* \otimes x^*$ and $(f \otimes g)^\dagger = f^\dagger \otimes g^\dagger$, and equipped with a unit and counit for the $*$ duality, natural morphisms satisfying the triangle identity. We also require

$$e_x^\dagger = i_{x^*}.$$

This expresses a relation between the two levels of duality, but we should emphasize that the relations between different levels of n -categorical duality are very poorly understood, and our treatment here is provisional. In any event, with this definition the morphisms in $C_{1,1}$ describe isotopy classes of framed (or equivalently, oriented) 1-tangles in 2 dimensions [34]. Composition of morphisms in this category corresponds to vertical juxtaposition of 1-tangles, while the tensor product corresponds to horizontal juxtaposition.

Continuing down to $k = 2$, we have braided monoidal categories. By a braided monoidal category ‘with duals’ we mean a monoidal category with duals which is also braided. We also require that the braiding and the ‘balancing’ shown in Figure 31 be unitary, where a morphism f is said to be unitary if $ff^\dagger = f^\dagger f = 1$.

31. The balancing in a braided monoidal category with duals

Turaev and Yetter [71, 73] have shown that the morphisms in $C_{1,2}$ correspond to isotopy classes of framed 1-tangles in 3 dimensions. Here a couple of remarks are in order. First, in this dimension, our sort of framing is equivalent to an orientation together with what is often called a framing in knot theory. Second, it is common to study 1-tangles in 3 dimensions using categories in which the existence of the

balancing is a separate postulate [20]. In our approach it arises automatically. In fact, this idea is already implicit in the work of Fröhlich and Kerler [35].

By a symmetric monoidal category ‘with duals’ we mean just a braided monoidal category with duals which is also symmetric. The morphisms in $C_{1,3}$ correspond to isotopy classes of framed 1-tangles in 4 dimensions, because $C_{1,3}$ is obtained from $C_{1,2}$ by adding the extra relations $B_{u,v} = B_{v,u}^{-1}$ for all u, v , corresponding to the fact that in 4 dimensions there is room to unlink all links. The same is true in all higher dimensions — as one would expect from the stabilization hypothesis. More generally, transversality results from differential topology imply that for $k \geq n + 2$, all embeddings of compact n -manifolds in \mathbf{R}^{n+k} are isotopic [40]. Given the tangle hypothesis, this is a powerful piece of evidence for the stabilization hypothesis.

In the $n = 2$ column we find the situation less well understood but still very promising. The precise definition of a k -tuply monoidal 2-category with duals has not yet been systematically worked out. Instead, work so far has focused on the relation between braided monoidal 2-categories with duals and 2-tangles in 4 dimensions. Carter, Saito and others have worked out a description of such 2-tangles as movies in which each frame is a 1-tangle in 3 dimensions, giving explicit ‘movie moves’ which go between any two movies representing isotopic 2-tangles [18]. Fischer [31] has used this information to describe a 2-category of 2-tangles in 4 dimensions, and came close to proving the tangle hypothesis in this case. There are a number of loose ends, however, and recently Kharlamov and Turaev [51] have done some careful work on this subject, particularly concerning the equivalence relation on 1-tangles in 3 dimensions needed to defining 1-morphisms as equivalence classes.

Rather than reviewing this work in detail, let us simply touch upon what may at first seem the most surprising feature, namely, how the various levels of duality interact to yield the 2-morphisms corresponding to the movies in Figure 6: the birth of a circle, death of a circle, and saddle point. This after all, is a crucial part of the tangle conjecture: that duality in n -categories naturally yields the correct handle attachments and handle cancellations in the Morse-theoretic description of n -tangles.

We expect the movies in Figure 6 to occur whenever $k \geq 1$, so for simplicity consider the case $k = 1$. In a monoidal 2-category with duals there should be 3 levels of duality: each object x should have a dual x^* , each morphism $f: x \rightarrow y$ should have a dual $f^\dagger: y \rightarrow x$, and each 2-morphism $\alpha: f \Rightarrow g$ should have a dual $\hat{\alpha}: g \Rightarrow f$. The dualities for objects and morphisms should have associated units and counits, but not the duality for 2-morphisms. Thus for any object x there are morphisms

$$i_x: 1 \rightarrow x \otimes x^*, \quad e_x: x^* \otimes x \rightarrow 1,$$

and for any morphism $f: x \rightarrow y$ there are 2-morphisms

$$\iota_f: 1_y \Rightarrow f f^\dagger, \quad \epsilon_f: f^\dagger f \Rightarrow 1_x.$$

The unit and counit for morphisms should satisfy the triangle identities, while the unit and counit for objects should probably satisfy them only weakly, i.e., up to the 2-isomorphisms shown as 2-tangles in 3 dimensions in Figure 32.

32. The 2-isomorphisms $1_x \Rightarrow (1_x \otimes e_x)(i_x \otimes 1_x)$ and $1_{x^*} \Rightarrow (e_x \otimes 1_{x^*})(1_{x^*} \otimes i_x)$ as 2-tangles in 3 dimensions

We also expect rules such as

$$\begin{aligned} (x \otimes y)^* &= y^* \otimes x^*, & (fg)^\dagger &= g^\dagger f^\dagger, & (\alpha\beta)^\wedge &= \hat{\beta}\hat{\alpha}, \\ x^{**} &= x, & f^{\dagger\dagger} &= f, & \hat{\hat{\alpha}} &= \alpha, \end{aligned}$$

and

$$e_x^\dagger = i_{x^*}, \quad \hat{\epsilon}_f = \iota_{f^\dagger}.$$

Then, as shown in Figure 33, the birth of a clockwise oriented circle corresponds to the unit of the counit of x , that is, $\iota_{e_x}: 1_1 \Rightarrow e_x e_x^\dagger$. Similarly, the death of a clockwise oriented circle corresponds to the counit of the unit of x , $\epsilon_{i_x}: i_x^\dagger i_x \Rightarrow 1_1$. One sort of saddle point is given by the unit of the unit of x , $\iota_{i_x}: 1_{x \otimes x^*} \Rightarrow i_x i_x^\dagger$, while another is given by the counit of the counit of x , $\epsilon_{e_x}: e_x^\dagger e_x \Rightarrow 1_{x^* \otimes x}$. Differently oriented versions of the 1-manifolds with boundary appearing here can be obtained by replacing x with x^* above.

33. The 2-morphisms $\iota_{e_x}, \epsilon_{i_x}, \iota_{i_x}$, and ϵ_{e_x} as 2-tangles in 3 dimensions

The reader may enjoy studying how the triangle identities for ι and ϵ translate into handle cancellations. For example, the following triangle identity, where \otimes denotes horizontal composition:

$$\begin{array}{ccc} i_x & \xrightarrow{1_{i_x}} & i_x \\ & \searrow \iota_{i_x} \otimes 1_{i_x} & \nearrow 1_{i_x} \otimes \epsilon_{i_x} \\ & & i_x i_x^\dagger i_x \end{array}$$

gives the isotopy between 2-tangles in 3 dimensions shown in Figure 34.

34. A 2-categorical triangle identity as 2-tangle isotopy

Proceeding down the $n = 2$ column in Figure 30, we observe the following features. Taking $k = 2$, a 2-morphism $\alpha: f \rightarrow g$ in $C_{2,2}$ should correspond to a 2-tangle in 4 dimensions, going from an equivalence class f of 1-tangles in 3 dimensions to another equivalence class g . The braiding phenomena arise from the fact that $C_{2,2}$ is a braided monoidal 2-category [18, 31]. The case $k = 3$ corresponds to 2-tangles in 5 dimensions. In Figure 30 we have shown such a 2-tangle going from a seemingly linked pair of circles to an unlinked pair. The point is that, thinking of the 5th dimension as time, any link in 4-dimensional space can be unlinked as time passes. In fact, an over-crossing can be isotoped to an under-crossing while pushing one strand either a little bit ‘up’ into the 4th dimension or a little bit ‘down’. Algebraically, since $C_{2,3}$ is weakly involutory, we expect these two distinct isotopies to correspond to $I_{x,y}: B_{x,y} \Rightarrow B_{y,x}^{-1}$ and $(I_{x,y}^{-1})_{hor}^{-1}: B_{x,y} \Rightarrow B_{y,x}^{-1}$. The case $k = 4$ corresponds to 2-tangles in 6 dimensions. In this dimension and higher dimensions, the two isotopies from an over-crossing to an under-crossing are themselves isotopic. This should correspond to the fact that in a strongly involutory monoidal 2-category, $I_{x,y} = (I_{x,y}^{-1})_{hor}^{-1}$.

Now, taken together, the stabilization hypothesis and tangle hypothesis suggest a proposal for the n -category of which n -dimensional extended TQFTs are representations:

Extended TQFT Hypothesis, Part I. The n -category of which n -dimensional extended TQFTs are representations is the free stable weak n -category with duals on one object.

The idea here is, first, that by the stabilization hypothesis $C_{n,k}$ should stabilize for $k \geq n + 2$, yielding what we call the ‘free stable weak n -category with duals on one object’, $C_{n,\infty}$. Topologically this suggests that when considering the category whose objects are framed 0-manifolds, whose morphisms are framed 1-manifolds with boundary, whose 2-morphisms are framed 2-manifolds with corners, and so on up to n , we are free to think of all these objects as embedded in $[0, 1]^{n+k}$ where $k \geq n + 2$. Thus in particular the n -morphisms can be thought of as isotopy classes of framed n -tangles in $n + k$ dimensions, where $k \geq n + 2$.

In the next section we turn to the implications of this hypothesis for topological quantum field theory; here we briefly summarize one more sophisticated piece of evidence for it. This comes from the connection between framed cobordism theory and stable homotopy theory [1, 70]. By the relation between the n -categorical and homotopy-theoretic notions of suspension, one expects the homotopy n -type of $\Omega^k S^k$ to correspond to a very special weak n -groupoid, namely the free k -tuply monoidal weak n -groupoid on one object, $G_{n,k}$. Now duals are simply a weakened form of inverses [45], so by the universal property of $C_{n,k}$ one expects there to be a weak n -functor $T: C_{n,k} \rightarrow G_{n,k}$ that turns duals into inverses. Topologically speaking, T should be given by the Thom-Poincaré construction. Indeed, this construction is implicit in Figure 26, where a tangle is used to describe a homotopy. Suppose, for example, that $\alpha = \beta$ is the generating object x of $C_{1,2}$. Then the tangle in Figure 26 is the morphism $B_{x,x}$ in $C_{1,2}$. On the other hand, Tx is the object in $G_{1,2}$, or point in $\Omega^2 S^2$, corresponding to identity map from S^2 to itself. Thus $TB_{x,x}$ is a morphism in $G_{1,2}$ corresponding to a nontrivial homotopy from $Tx \otimes Tx$ to itself.

More generally, define a ‘ j -loop’ in any monoidal n -category to be an j -morphism from 1_{j-1} to 1_{j-1} , where we define the object 1_0 to be the unit for the monoidal structure and, recursively, $1_{i+1} = 1_{1_i}$. Now T should map j -loops in $C_{n,k}$ to j -loops in $G_{n,k}$. In particular, an n -loop in $C_{n,k}$ is just an isotopy class of compact framed j -manifolds embedded in $[0, 1]^{n+k}$ (or equivalently S^{n+k}). On the other hand, an n -loop in $G_{n,k}$ is an element of $\pi_{n+k}(S^k)$. There is indeed a map from the former to the latter, given by the Thom-Pontryagin construction. Now for $k \geq n + 2$, $G_{n,k}$ should stabilize to a weak n -groupoid $G_{n,\infty}$ representing the homotopy n -type of the infinite loop space $\Omega^\infty S^\infty$, so we expect to obtain a weak n -functor $T_\infty: C_{n,\infty} \rightarrow G_{n,\infty}$. By the universal property of $G_{n,\infty}$, this n -groupoid should simply be the result of adjoining formal inverses to all j -morphisms in $C_{n,\infty}$. One expects from this that the i th framed cobordism group is isomorphic to $\pi_i(\Omega^\infty S^\infty)$, that is, the i th stable homotopy group of spheres. This is indeed the case!

Extended TQFTs

One can think of n -category theory as providing a natural hierarchy of generalizations of set theory. The basic idea is that the mathematics of sets, regarded as the study of the category Set , leads us to consider general categories. Regarding this as the study of the 2-category Cat we are then lead to consider general 2-categories, and so on. In general, the category $n\text{Cat}$ of small strict n -categories is a strict $(n + 1)$ -category, and we expect something of a similar but more sophisticated sort to hold for weak n -categories. At each level of this hierarchy one can do abstract algebra, which at the n th level is intimately tied to n -dimensional topology. To describe an

extended TQFT as a representation of an n -category, we must also develop analogs of linear algebra at each level.

In physics, linear algebra is usually done over \mathbf{R} or \mathbf{C} , but for higher-dimensional linear algebra it is useful to start more generally with any commutative ‘rig’, or ‘ring without negatives’. This is a set R equipped with two commutative monoid structures, written $+$ and \cdot , satisfying the distributive law $a \cdot (b + c) = a \cdot b + a \cdot c$. A good example of such a thing without additive inverses is the natural numbers (including zero), and one reason we insist on such generality is to begin grappling with the remarkable fact that many of the important vector spaces in physics are really defined over the natural numbers, meaning that they contain a canonical lattice with a basis of ‘positive’ elements [28]. Examples include the weight spaces of semisimple Lie algebras, fusion algebras in conformal field theory [35], and thanks to the work of Kashiwara and Lusztig on canonical bases, the finite-dimensional representations of quantum groups [20, 22].

Linear algebra over the commutative rig R can be thought of as the study of the category \mathbf{Vect} of ‘vector spaces’ over R , by which we simply mean R -modules isomorphic to R^k for some k . Now \mathbf{Vect} itself has two symmetric monoidal structures corresponding to the direct sum \oplus and tensor product \otimes of vector spaces, and the tensor product distributes over direct sum up to a natural isomorphism satisfying certain coherence laws. Thus \mathbf{Vect} is a categorical analog of a rig, which one might call a ‘rig category’. These are often called ring categories, but there need be no additive inverses. Precise definitions and strictification theorems for these have been given by Laplaza [53] and Kelly [48].

The analogy between the commutative rig R and the symmetric rig category \mathbf{Vect} suggests the existence of a recursive hierarchy of ‘ n -vector spaces’. For example, the categorical analog of an R -module is a ‘module category’ over \mathbf{Vect} . This is a category V equipped with a symmetric monoidal structure \oplus and a functor $\otimes: \mathbf{Vect} \times V \rightarrow V$ satisfying the usual conditions for a module up to natural isomorphisms satisfying various coherence laws. The module categories of special interest, the ‘2-vector spaces’, are those equivalent as module categories to the k -fold Cartesian product \mathbf{Vect}^k . A careful study of these has been done by Kapranov and Voevodsky [46]. The primordial example of a 2-vector space is \mathbf{Vect} itself, but when $R = \mathbf{C}$ a more interesting example is the category of representations of a semisimple algebra. In general one hopes to define a weak $(n+1)$ -category $(n+1)\mathbf{Vect}$ of ‘ $(n+1)$ -vector spaces’ over R having as objects ‘module n -categories’ over $n\mathbf{Vect}$ which are n -equivalent, as module n -categories, to $n\mathbf{Vect}^k$ for some k . Moreover, $(n+1)\mathbf{Vect}$ should be a monoidal — in fact stable — $(n+1)$ -category, permitting one to define module $(n+1)$ -categories over it and to continue the recursive definition. The primordial example of an $(n+1)$ -vector space should, of course, be $n\mathbf{Vect}$.

Much remains to be done to develop a full-fledged rigorous theory of higher-dimensional linear algebra. Indeed, attempting to develop it without a well-established theory of weak n -categories is rather like developing linear algebra without solid foun-

dations in set theory (which of course is historically what occurred). Nonetheless, it is already becoming evident from examples that the sense in which n -dimensional extended topological quantum field theories are ‘representations’ of some n -category is that they are weak n -functors from it to $n\text{Vect}$.

Note that while Vect is a stable 1-category, Hilb is a stable 1-category with duals, and that the 2 levels of duality this entails are both crucial in the definition of a unitary TQFT. As Freed [32] has pointed out, one can, at least for low n so far, develop a theory of ‘ n -Hilbert spaces’. Taking our basic rig to be \mathbf{C} , recall that associated to any vector space V there is, in addition to the dual V^* , the vector space \overline{V} having the same additive structure but on which \mathbf{C} acts in a complex-conjugated manner. A Hilbert space is then a vector space equipped with an inner product, a linear map

$$\langle \cdot, \cdot \rangle: \overline{V} \otimes V \rightarrow \mathbf{C}$$

that satisfies a nonnegativity condition and is also nondegenerate, meaning that by duality it yields an isomorphism $\overline{V} \cong V^*$. Similarly, associated to a 2-vector space there is the dual $V^* = \text{hom}(V, \text{Vect})$, defined using the appropriate notion of ‘hom’ for 2-vector spaces, and also \overline{V} , the opposite category of V (i.e., having the direction of all morphisms reversed). A 2-Hilbert space V should thus be a 2-vector space equipped with an inner product, that is, a functor

$$\langle \cdot, \cdot \rangle: \overline{V} \otimes V \rightarrow \text{Vect}.$$

This should be linear in the appropriate sense. Nonnegativity will be automatic because the rig category Vect has no negatives, but we should require nondegeneracy, meaning that the inner product should define an equivalence of Vect -modules between \overline{V} and V^* . (That these are equivalent has already been established by Yetter [74].) With still further conditions giving V some of the properties of Hilb , it appears that one obtains a notion of ‘2-Hilbert space’ such that 2Hilb is a stable 2-category with duals. Examples should certainly include the category of representations of a finite-dimensional C^* -algebra, such as the group algebra of a finite group [32].

We hypothesize, therefore, that we can recursively define a stable weak n -category with duals, ‘ $n\text{Hilb}$ ’, such that the following holds.

Extended TQFT Hypothesis, Part II. An n -dimensional unitary extended TQFT is a weak n -functor, preserving all levels of duality, from the free stable weak n -category with duals on one object to $n\text{Hilb}$.

The best evidence for this so far is the work of Freed and Quinn on the Dijkgraaf-Witten model [32, 33], of Lawrence on extended TQFTs defined via triangulations [54], and of Walker [72] on Chern-Simons theory. If this hypothesis is true, one should be able to specify an n -dimensional unitary extended TQFT simply by specifying a particular n -Hilbert space, thanks to the universal property of the stable weak n -category with duals on one object. (More precisely, this should specify a weak n -

functor up to ‘equivalence’ of these, a notion so far understood only for low n .) In future work we intend to describe the n -Hilbert spaces giving rise to various well-known TQFTs.

Quantization

To paraphrase Nelson, quantization is a mystery, not a functor. And indeed, while in some technical sense we understand how quantum groups give precisely the algebraic structures needed to construct 3-dimensional TQFTs, and how the ‘quantization’ of the group corresponds to the passage from classical to quantum field theory, we do not yet know to what extent this miracle can be generalized to higher dimensions. The search for algebraic structures appropriate for 4-dimensional TQFTs is already underway, with Donaldson theory as a powerful lure [18, 22, 23, 24, 54]. One would like higher-dimensional algebra to offer some guidance here, and eventually one would very much like a comprehensive picture of quantization for topological field theories in *all* dimensions.

In its simplest guise, quantization concerns the relation between the commutative algebras of observables in classical mechanics and the noncommutative algebras in quantum mechanics. On the one hand, one can start with a commutative algebra A and try to obtain a noncommutative algebra by ‘deformation quantization’. There is in general no systematic procedure for doing this. Nonetheless, one can study the possibilities, for example by considering algebra structures on $A[[\hbar]]$ given by formal power series

$$a \star b = ab + \hbar m_1(a \otimes b) + \hbar^2 m_2(a \otimes b) + \dots$$

The requirement that this ‘star product’ makes $A[[\hbar]]$ into an algebra imposes conditions on the m_i which can be studied using homological algebra [11]. Most simply, the quantity

$$\{a, b\} = m_1(a \otimes b) - m_1(b \otimes a),$$

which measures the first-order deviation from commutativity of the star product, must be a Poisson bracket on A , i.e. a Lie bracket with

$$\{a, bc\} = \{a, b\}c + b\{a, c\}.$$

On the other hand, there is an obvious way to get a commutative algebra from a noncommutative algebra A , namely by taking its center $Z(A)$. Physically this corresponds to extracting the classical part of a quantum theory, the so-called ‘superselection rules’. Note that taking the center, while a perfectly systematic process, is *not* a functor, since a homomorphism $f: A \rightarrow B$ need not restrict to a homomorphism from $Z(A)$ to $Z(B)$.

Figure 21 sheds some light on these ideas and their generalizations. In the $n = 0$ column one has, in the $k = 1$ and $k = 2$ rows, monoids and commutative monoids respectively. A monoid object in \mathbf{Vect} is an algebra, while a commutative monoid object is a commutative algebra. In addition to the forgetful functor from the category of commutative algebras to that of algebras, we have seen there are two nonfunctorial, but still very interesting, processes relating these categories: ‘taking the center’ and ‘deformation quantization’.

These processes have analogs in other columns of Figure 21. As one marches down any column, one expects the last step before stabilization to consist of imposing *equations* on structure already present. In this situation one can consider formal deformations of the stabilized sort of structure in the category of not-quite-stabilized structures. For example, in the $n = 1$ column one can consider deformations of a symmetric monoidal category in the category of braided monoidal categories. This is precisely where quantum groups arise! The category of representations of a Lie group is a symmetric monoidal category object in $2\mathbf{Vect}$, while the category of representations of the corresponding quantum group is a braided monoidal category object in $2\mathbf{Vect}$. The latter is a kind of deformation of the former in which, for example, the braiding is given by a formal power series

$$B_{x,y}(a \otimes b) = b \otimes a + \hbar r_1(a \otimes b) + r_2(a \otimes b) + \dots$$

The condition that B be a braiding imposes conditions on the r_i ; for example, r_1 must be a solution of the ‘classical Yang-Baxter equations’. For a detailed treatment of the ‘deformation quantization’ of symmetric monoidal categories into balanced braided monoidal categories, see Mattes and Reshetikhin [59]. The tangle invariants arising this way can be expanded as formal power series in \hbar , and the coefficients, known as ‘Vassiliev invariants’ or ‘invariants of finite type’, have special topological properties [9, 13]. Their relation with the deformation quantization of commutative algebras is clarified by the manner in which they arise in Chern-Simons perturbation theory [2].

The operation of ‘taking the center’ can also be generalized, in a subtle and striking manner. We can think of a k -tuply monoidal n -category C — strict, semistrict, or weak — as an object in the corresponding version of $(n + k)\mathbf{Cat}$. Let $Z(C)$ be the largest sub- $(n + k + 1)$ -category of $(n + k)\mathbf{Cat}$ having C as its only object, 1_C as its only morphism, 1_{1_C} as its only 2-morphism, and so on, up to only one k -morphism. Thus $Z(C)$ is a $(k + 1)$ -tuply monoidal n -category.

In what sense is $Z(C)$ the ‘generalized center’ of C ? Consider first the case where C is a monoid, thought of as a category with one object. Then $Z(C)$ is the largest sub-2-category of \mathbf{Cat} having C as its only object, the identity functor 1_C as its only morphism, and natural transformations $\alpha: 1_C \Rightarrow 1_C$ as 2-morphisms. In other words, $Z(C)$ is the commutative monoid consisting of all natural transformations $\alpha: 1_C \Rightarrow 1_C$. Since there is only one object in C , such a natural transformation is simply a single morphism in C , and the commutative square condition in eq. (4) implies this morphism must commute with all the other morphisms in C . Thus $Z(C)$ is just the

center of C as traditionally defined. This also shows that Z is not a functor.

We leave it to the reader to check that if C is a set, $Z(C)$ is the monoid consisting of all functions $F: C \rightarrow C$. Similarly, if C is a category, $Z(C)$ is the monoidal category whose objects are functors $F: C \rightarrow C$ and whose morphisms are natural transformations between such functors. The monoidal structure here corresponds to composition of functors. A more interesting example was worked out by Kapranov and Voevodsky [46]. Suppose that we start with a monoidal category C and work in the semistrict context. The 2-morphisms in 2Cat are known as ‘quasinnatural transformations’, since the square in eq. (4) is required to commute only up to a 2-isomorphism [38]. The 3-morphisms in 2Cat are known as ‘modifications’. The generalized center $Z(C)$ thus turns out to be the braided monoidal category whose objects are quasinnatural transformations $\alpha: 1_C \Rightarrow 1_C$ and whose morphisms are modifications between these.

It turns out that when C is the monoidal category of representations of a Hopf algebra H , $Z(C)$ is the braided monoidal category of representations of a Hopf algebra called the quantum double of H [20]. Moreover, while not themselves quantum doubles, quantum groups are easily constructed as quotients of quantum doubles [20]. We thus see that that in the $n = 1$ column of Figure 21, interesting braided monoidal categories can be obtained either by deformation quantization of symmetric monoidal categories, or by taking the generalized center of monoidal categories. We expect a more complex version of this story to occur in the higher- n columns. For example, in the $n = 2$ column there should be a theory of deformations of a strongly symmetric monoidal 2-category in the category of weakly symmetric ones. From Figure 30 one would expect this to be related to a Vassiliev theory for surfaces embedded in \mathbf{R}^5 . The generalized center construction should also be interesting. For example, one can obtain braided monoidal 2-categories as the generalized centers of monoidal 2-categories [7].

Acknowledgements

We would like to thank Lawrence Breen, Ronald Brown, Louis Crane, André Joyal, Thomas Kerler, Ruth Lawrence, Stephen Sawin, Bruce Smith, Ross Street, Dominic Verity, and David Yetter for helpful discussions and correspondence.
