Housewife, "Gold Miss," and Equal: The Evolution of Educated Women's Role in Asia and the U.S.

Jisoo Hwang*

November 10, 2012

JOB MARKET PAPER

Abstract

The fraction of U.S. college graduate women who ever marry has increased relative to less educated women since the mid-1970s. In contrast, college graduate women in developed Asian countries have had decreased rates of marriage, so much so that the term "Gold Misses" has been coined to describe them. This paper argues that the interaction of rapid economic growth in Asia combined with the intergenerational transmission of gender attitudes causes the "Gold Miss" phenomenon. Economic growth has increased the supply of college graduate women, but men's preference for their wives' household services has diminished less rapidly and is slowed by women's role in their mothers' generation. Using a dynamic model, I show that a large positive wage shock produces a greater mismatch between educated women and men in the marriage market than would gradual wage growth. I test the implications of the model using three data sets: the Japanese General Social Survey, the American Time Use Survey, and the U.S. Census and American Community Survey. Using the Japanese data, I find a positive relationship between a mother's education (and employment) and her son's gender attitudes. In the U.S., time spent on household chores among Asian women is inversely related to the female labor force participation rate in husband's country of origin. Lastly, college graduate Korean and Japanese women in the U.S. have greater options in the marriage market. They are more likely to marry Americans than Korean and Japanese men do, and this gender gap is larger among the foreign born than the U.S. born.

I am grateful to Alberto Alesina, Raj Chetty, Claudia Goldin, and Lawrence Katz for their guidance and feedback throughout this project. I would also like to thank Wenxin Du, John Friedman, Paola Giuliano, Edward Glaeser, Seok Ki Kim, Joana Naritomi, Claudia Olivetti, Amanda Pallais, Dana Rotz, László Sándor, Anitha Sivasankaran, and seminar participants at Harvard University for helpful comments and discussions. This project received financial support from the Lab for Economic Applications and Policy at Harvard University. All remaining errors are my own.

1 Introduction

Marriage rates have decreased among women in Japan, South Korea (hereafter Korea), Taiwan, Singapore, and Hong Kong during the past several decades. As covered in a recent article in *The Economist*, "The Asian avoidance of marriage is new, and striking. ... In South Korea, young men complain that women are on marriage strike."[1] The majority of women on this "marriage strike" are highly educated, four-year college graduates. Koreans call this growing group of educated single women "Gold Misses."[2]

Later marriages are common among the educated worldwide. What is striking about the phenomenon in Asia, however, is that Gold Misses are not merely delaying marriage. Rather, they are remaining single and at a much higher cost than in the West. Cohabitation is rare and out-of-wedlock childbirths make up less than 2 percent of total childbirths in Korea and Japan.[3] Moreover, the gap in marriage rates between college graduate and non-college graduate women has not diminished in Asia—it has grown. In the U.S., in contrast, the gap narrowed and reversed in the mid-1970s.[4]

Why are there Gold Misses and why are they increasing in developed Asia? This paper argues that the interaction of Asia's rapid economic growth combined with the intergenerational transmission of gender attitudes causes the Gold Miss phenomenon. Wage growth creates incentives for more women to become educated and to participate in the labor market. However, gender norms do not shift at once; they are passed from one generation to the next. Men are still accustomed to women being housewives as in their mothers' generation and have preference for wives' household services. Thus, some educated women choose to remain single rather than marry "traditional" men.

The story sketched above emerges from a simple dynamic model of intergenerational transmission of gender attitudes, in which the fraction of men with preference for wives' household time decreases with the fraction of educated women in the previous generation. Women's education, marriage, and household time allocation decisions are functions of the endogenously evolving preferences within the male population.[5] The model predicts that Gold Misses are more likely to arise in economies that experience rapid, rather than gradual,

[1] *The Economist*, "The flight from marriage," August 20th 2011.

[2] Terms have been coined in each region to refer to this group—in Korean *Gold Miss* (because they are "old misses" but highly educated and financially independent), in Japanese *Hanako-zoku* (literally "Hanako tribe," named after the readers of the consumer magazine *Hanako*, which targets young single women) or *Wagamama* (translated as "single parasites" because most unmarried adults live with their parents), and in Chinese *Shengu* (translated as "leftover women"). Among these, I choose to use the term Gold Miss throughout this paper.

[3] Korea and Japan are ranked the two lowest among OECD countries in out-of-wedlock childbirths. 38 percent of births are out-of-wedlock in the U.S. (OECD Family Database, 2011)

[4] See Figure 4. For references on the trends of U.S. college graduate women's marriage and fertility, see for example, Kalmijn (1991), Goldin (2004), Schwartz and Mare (2005), Stevenson and Wolfers (2007) and Shang and Weinberg (2012).

[5] c.f., Fernandez, Fogli and Olivetti (2004).

growth in women's wages.

To empirically evaluate this hypothesis, I use three different datasets. First, I use the Japanese General Social Survey to explore the gender attitudes and marriage patterns of Japanese men. Second, I use the American Time Use Survey to study time allocation at home among married couples in the U.S. by their country of origin and generation since migrating to the U.S. Lastly, I use the U.S. census data to analyze marriage patterns of men and women from two major Gold Miss countries—Korea and Japan.

I find evidence consistent with the implications of my model. First, men's gender attitudes are affected by the economic status of women in their parents' generation. Men in Japan who had working or college graduate mothers during childhood have more egalitarian views regarding gender roles, and are more likely to have working wives. Among U.S. immigrants from countries with low female labor force participation (LFP) rates, U.S. born men spend about 1 hour per week more on housework relative to foreign born men, and reduce their wives' time spent on housework by 4 hours per week.

Second, women marry "less traditional" men (rather than "traditional") when they are available. In Japan, the probability that a college graduate man ever marries is positively correlated with his mother's LFP. Among Koreans and Japanese residing in the U.S., foreign born women are 20 percentage points more likely than their male peers to marry a non-Korean or non-Japanese. I exploit regional variation in the composition of male population to show that Korean and Japanese women are more likely to marry out of their ethnic group when the foreign born share is higher among Korean and Japanese men.

Third, the increase in Gold Misses is less severe when the fraction of "less traditional" men in the marriage market is larger. In contrast to Korea and Japan, I find that college graduate Korean and Japanese women in the U.S. are as likely to be married as the non-college graduates.

The results indicate that educated women's marriage prospects are better when the generation gap in women's educational attainment (and LFP) is smaller. This offers new insight into the forces underlying the evolution of educated women's role. Previous studies have focused on the supply-side determinants such as the introduction of the pill, the opening up of co-ed universities, and the advancements in household appliances technology.[6] These changes enabled the supply of educated and working women to increase in the marriage market. However, this paper demonstrates that an equally important determinant is the demand-side—whether men *want* educated and working wives who outsource housework—and thereby shows how women's role may not transition smoothly from housewife to equal even with economic growth.[7] I also add to the line of research on cultural norms by providing

[6]See for example, Goldin and Katz (2002), Goldin and Katz (2011), Greenwood, Seshadri and Yorukoglu (2005), and Greenwood and Guner (2009).

[7]Feyrer, Sacerdote and Stern (2008) share similar intuitions, although they do not present a formal model. Looking at cross-country differences in fertility rates, they argue that countries where women's household

an example of how rigid gender roles may weaken in response to changes in women's relative wages, and research on the assimilation of immigrants by explaining why there may be significant gender gaps in marital assimilation.[8]

The remainder of the paper is organized as follows. Section 2 provides an overview of the Gold Miss phenomenon with statistics from developed Asian countries. Section 3 presents the dynamic model. Section 4 lays out the empirical results. Section 5 concludes.

2 Background: The Gold Miss Phenomenon in Asia

Gold Miss (and analogous terms used in Asia, see footnote 2) colloquially means a never married woman in her thirties or older who has received at least a four-year college education, has her own career, and earns a higher-than-average yearly income. She is not just a "Miss," she is a rich one. In order to use one general standard for different countries, in this paper I define Gold Miss as a *four-year college graduate woman over age 35 who has never married*.[9] The Gold Miss phenomenon then refers to the increase in the share of college graduate women who have never married relative to that of non-college graduate women.

The Gold Miss countries are the East Asian "tiger economies" that achieved economic miracles over the past half-century. Figure 1 depicts the historical trend of GDP per capita in Hong Kong, Japan, Korea, Singapore, and Taiwan in comparison to the U.S. and the world average from 1900 to present. The growth trajectories of the Asian economies share a common pattern—rapid economic development from the 1960s onward (with growth rates in excess of 7 percent a year). The U.S. has had a higher GDP per capita than Asia since the early 20th century and follows a more gradual growth path throughout.

Industrialization opened up (and benefited from) new opportunities for women. According to the United Nations statistics for 1985–2006 on labor force participation (LFP) rates of women in the age group 25–34, the U.S. begins at around 70 percent. Rates in Japan, Korea, and Singapore begin much lower (56.6 percent, 39.2 percent, and 58.3 percent, respectively). The Asian rates then increased by more than 17 percentage points from 1985 to 2006; the U.S. rates increased by 5 percentage points.

Educational attainment shows a similar pattern. There were virtually no college graduate

status lags behind their labor market opportunities experience the lowest fertility rates.

[8]See for example, Giuliano (2007), Fernandez and Fogli (2009), Alesina and Giuliano (2010), Alesina, Nunn and Guiliano (2011) for discussions on the persistence of family culture. Regarding assimilation profiles by gender, Blau and Kahn (2007) study Mexican immigrants in the U.S. and find dramatic assimilation in labor supply for female immigrants.

[9]Age thirty-five is young enough to capture recent developments and old enough to distinguish between "marriage delayed" and "marriage forgone" among women in Asia. Despite the rise in women's age at first marriage—29 in Japan and Korea, 28 in Taiwan, 30 in Hong Kong, and 28 in Singapore (Jones and Gubhaju (2009))—marriage rates fall starkly once women reach their late thirties. The age-specific marriage rate for brides in age group 35–39 is only 12.2 (per thousand) in Korea and 9.2 (per thousand) in Japan (Statistics Korea, 2010 and Vital Statistics of Japan, 2009). The peak is at ages 25–29 for brides in both countries.

women in East Asia before World War II. However, with economic growth and education reforms, tertiary enrollments greatly increased.[10] Figure 2 shows college enrollment rates in Japan and Korea by sex. In Japan, although the college gender gap persists, women's college enrollment rates rose from near zero in 1955 to 41 percent in 2007. In Korea, women's enrollment rates increased from 20 percent to 55 percent in just 18 years and the college gender gap has disappeared.

Despite the transformation in women's LFP and education, marriage prospects for educated women in developed Asian nations have evolved quite differently from that of the West. Figure 3 depicts the fraction ever married among men and women in their late 30s in Hong Kong, Japan, Korea, Singapore, and the U.S. by education level. In all four Asian countries, higher education increases the marriage probability for men but lowers the marriage probability for women. The consequences are twofold: the least educated men are left single unless they "import" brides from, for example, developing South Asian countries, and highly educated women remain unmarried and become Gold Misses.[11] In the U.S., on the other hand, education has a positive relationship with marriage probability for both men and women.

The negative education gradient for women in Asia has even become steeper than in the past. Figure 4 plots the difference in fraction ever married between college graduates and non-college graduates in each birth cohort, among men and women over age 35 in Hong Kong, Japan, Korea, and the U.S.[12] Panel A shows that for men, college graduates' marriage probabilities increased relative to non-college graduates.' Panel B shows that for women, not only are college graduates less likely to be ever married than non-college graduates, but the gap has widened over time in Asian countries. For the most recent 1970s birth cohort, the difference amounts to 14 percentage points in Hong Kong and 5 percentage points in Japan and Korea. This contrasts with the upward slope in the U.S.: the difference in fraction ever married between college and non-college women has switched from negative to positive for American women.

[10] In Japan, the largest education reform took place during the U.S. Occupation after World War II. The sex-segregated education system was reformed to a single-track system and women's colleges and universities were established. From 1960 to 1970, the government succeeded in more than doubling the number of science and engineering university faculties. In Korea, the quota on enrollment at public and private tertiary institutions was relaxed in the 1980s and a new national standardized preliminary test was introduced to replace individual college admission tests. The government also accredited more private colleges to meet the demands of the labor market.

[11] See Kawaguchi and Lee (2012) for a discussion about female migration from developing Asian countries to developed East Asian countries. They find that foreign brides currently comprise 4 to 35 percent of newlyweds in Japan, Korea, Singapore, and Taiwan although there is no raw sex ratio imbalance in these countries. Men with low socioeconomic statuses marry foreign women.

[12] Singapore and Taiwan do not provide Census micro-data. Including all individuals over age 35 may overstate the marriage rates of earlier cohorts since they are being observed at later ages than recent cohorts. The bias is expected to be relatively unimportant, however, since first marriages are rare once women reach their late thirties. (See footnote 9 for more detail.)

How do the Asian college graduate women of earlier and later cohorts differ? One major difference is in their careers. College graduate women in Asia are now not only working but are also increasingly taking on professional full-time occupations once considered to be men's. For instance, the fraction female among managerial/professional workers in Korea was 0.19 in 1971 but is now 0.41 (Economically Active Population Survey). The female-to-male median earnings of full-time employees in Japan increased from 45 percent in 1954 to 64 percent in 2006 and in Korea from 42 percent in 1975 to 67 percent in 2009. Appendix Figure A1 shows the contrast with the earlier development in the U.S.

Women's new roles imply conflict for Asian families. Confucian ethics prescribe gender norms in all Gold Miss countries that for centuries described the ideal woman as a "good wife, wise mother."[13] Despite the growing number of dual-earner households, the belief that women should be responsible for child rearing and housework continues. Arranged marriage has nearly disappeared but marriage is still considered a union of two families (rather than just the man and the woman). Hence, relatives and parents (in-laws) are continuously watching over the married couple's life. Pre-marital cohabitation and out-of-wedlock childbirths are socially stigmatized.

According to the 2005–2008 World Value Survey, the percentage of people who disagreed with the statement "When jobs are scarce, men should have more right to a job than women" is 66.4 percent in the U.S., but only 44.2 percent in Hong Kong, 17.9 percent in Japan, 26.4 percent in Korea, and 36 percent in Taiwan.[14] To the statement "It is more important for a wife to help her husband's career than to have one herself," 70.4 percent of Americans disagreed (General Social Survey) whereas the percentage of respondents who disagreed is less than half of that in Asia—22.9 percent in Japan, 35 percent in Korea, and 31.2 percent in Taiwan (East Asian Social Survey).[15]

Time Use Survey findings confirm these beliefs. Among dual-earner households, women's average time spent on household activities is at least 2 hours (per day) longer than men's in Japan and Korea (Japanese Time Use Survey, 2006 and Korean Time Use Survey, 2009).[16]

[13] *ryōsai kenbo* in Japanese, *hyun mo yang ch'o* in Korean, and *xián qī liáng mù* in Chinese.

[14] Possible answers are (1) Agree, (2) Disagree, and (3) Neither. (Don't know and missing are excluded.) The sample size for each country is U.S. 1,238, Hong Kong 1,225, Japan 1,042, Korea 1,197, and Taiwan 1,226. No statistics are available for Singapore on this question.

[15] Possible answers are (1) Strongly agree, (2) Agree, (3) Disagree, and (4) Strongly disagree in the GSS and (1) Strongly agree, (2) Fairly agree, (3) Somewhat agree, (4) Neither agree or disagree, (5) Somewhat disagree, and (6) Strongly disagree in the EASS. (Don't know and missing are excluded.) The sample size for each country is U.S. 13,748, Japan 2,130, Korea 1,605, and Taiwan 2,102. EASS is a cross-national network of GSS-type surveys in East Asia and is distributed by the EASS Data Archive. Singapore and Hong Kong are not included.

[16] The Japanese Time Use Survey is conducted by the Bureau of Statistics and covers household members older than age 10 in 99,000 households nationwide. "Housework" is a separate category from "Child care" and "Nursing" and includes activities such as food preparation, cleaning, caring for family members other than children, keeping the family account, and visits to the public office on personal or family matters. Korea's Time Use Survey is collected by the National Statistical Office and covers household members older than age 10 in 8,100 households nationwide. "Household Activities" corresponds to the same category in

Gender gap exists in the U.S. as well, but the magnitude is much smaller—50 minutes per day (American Time Use Survey, 2003–2011).

There is virtually no difference in household appliances technology between the Gold Miss countries and other developed countries. The relative price of hiring a live-in domestic worker in the U.S. and in East Asia is also comparable, at about 40 percent of the mean wage of native college graduate women. In fact, the price is lower in Taiwan and Singapore, and particularly lower in Hong Kong, than in the U.S.[17]

Thus, although the Gold Miss phenomenon may look similar with what occurred in the U.S. and elsewhere when women first began to graduate from college, there are important differences. In the early twentieth century, women could not easily have both family and career with the (lack of) contraceptive methods, household appliances technology, market substitutes for household production, and labor market opportunities (Goldin (2004)). As surveyed in this section, women in developed Asia today do not face these conditions. Rather, the constraints of marriage derive from traditional household roles families expect from the wife and daughter-in-law.

3 Model of the Intergenerational Transmission of Gender Attitudes and of Marriage

Building on the framework of Fernandez, Fogli and Olivetti (2004), I develop a simple dynamic model where women's education, marriage, and labor force participation decisions are functions of wages and the endogenously evolving types within the male population—"traditional" and "modern." I define a man as traditional if he has preference for his wife's household services and modern if he is willing to substitute wife's housework with his own or with market goods and services. The fraction of modern men increases with the fraction of educated women in the previous generation.

When women's wages rise, more women choose to stay single than marry traditional husbands. The key distinguishing prediction of this model is the path dependency of the Gold Miss phenomenon. Given that men initially hold traditional values, economies where women's wages increased rapidly are more likely to experience the Gold Miss phenomenon

the Bureau of Labor Statistics time use data. Activities such as housework, food and drink preparation and clean-up, interior maintenance, exterior maintenance, vehicle maintenance, and household management are included. It does not include time spent on caring for children or other family members.

[17]Hong Kong has a foreign domestic worker (FDW) program and the government sets the minimum wage for these workers. According to Cortes and Pan (forthcoming), the minimum wage is more than four times lower than high skilled women's wage. Though limited, Taiwan and Singapore have similar programs; the FDW's wage is about 30–40 percent of native college graduate women's. Japan and Korea have stricter immigration policies. The relative price of live-in domestic workers is nearly half of native college graduate women's wage, as in the U.S. (See Huang, Yeoh and Rahman (2005) for more information on foreign domestic workers.)

compared with economies where women's wages increased gradually over time. In the rapid case, a large discrepancy appears between the women's roles when men were growing up and women's roles in their own cohort. As a result, there are not enough modern men for the newly educated women to marry.[18]

I make the following assumptions for tractability. Women differ in their effort costs of becoming educated and can choose to invest in education ("educated," E) or not ("uneducated," U). If a woman invests in her education, she gets wage w_E in the labor market, which is higher than the wage she would get if uneducated, w_U. w_E is randomly drawn from a distribution that varies exogenously over time. Men, on the other hand, are assumed to have homogeneous skill level and earn w_m in the labor market.[19] Men differ in their cultural upbringing: those who grew up around educated women develop less traditional gender attitudes ("modern," M) compared with those who grew up around housewives ("traditional," T). All agents are rational and forward-looking.

The timing in the model is as follows. In the first period, women decide whether or not to become educated. In the second period, men and women are randomly matched and decide whether to get married or remain single. In the third period, men and women decide on a time allocation between market activity and household production. Below I describe the intergenerational dynamics and then solve for each stage of the decision-making process.

3.1 Intergenerational Dynamics

Gender attitudes (or more specifically, men's preferences for wives' household services) are transmitted from mother to son. Assuming, as is reasonable for Asia, that only married women have children, the fraction of modern men (λ_M) in cohort t then depends on the fraction of married educated women in the previous cohort. The dynamics of the system are thus given by:

$$\lambda_{Mt+1}(\lambda_{Mt}) = p_{Et}(\lambda_{Mt})\lambda_{Et}(\lambda_{Mt}) \tag{1}$$

[18]Standard models of household production can also show that growth in women's earning power reduces the gain from marriage or that positive assortative mating becomes optimal as technology advances (Becker (1991)). However, they cannot explain why marriage patterns would evolve differently across similarly developed countries. Intra-household models also face this limitation if bargaining power is a function of only wages. (See Chiappori and Donni (2011) for a survey of this literature.) Assuming that the sharing rule is affected by other "distribution factors," in which gender attitudes can be a component, is an option. The difference with my model would then be that the husband's type affects the wife's utility via consumption.

[19]If men also differed in their educational attainment and wages, there would be four categories of men, with the modern and educated being the most attractive husband and the traditional and uneducated being the least attractive. Figure 3 Panel A and Kawaguchi and Lee (2012) address this outcome. Since my paper's focus is on the Gold Misses, I do not add the education dimension to men. But the traditional and uneducated men not being able to marry is a by-product of the Gold Miss phenomenon, and can thus be explained by the same mechanisms.

where p_{Et} is the marriage probability of educated women and λ_{Et} is the fraction of educated women at t (both are functions of λ_{Mt}).[20]

This intergenerational linkage can be supported by at least two different mechanisms. First, parents exert a direct socialization effort to influence their children's process of preference formation. This is similar to the idea of "direct vertical socialization" discussed in Bisin and Verdier (2000). Educated mothers teach their sons that a family can function well with substitutes of her time.

Second, people tend to imitate others and like those who are similar to themselves, as is well-documented in research on peer effects, discrimination, and social norms. (See for example, Becker (1957) and Akerlof and Kranton (2000)). Even if mothers do not teach specific values to their children, boys are likely to emulate their parents or other role models when they form their own families.[21]

Whichever mechanism is at work (or most likely, a combination of these mechanisms), the dynamics can be expressed as equation (1) in reduced form.[22] Note that since preferences are formed during childhood, men cannot freely choose to be one type or the other (the cost of changing one's attitudes is very high).

3.2 Household Decision

All individuals are endowed with a unit of time. Within a married household, each spouse decides how much time t to allocate to market activity; the remaining time $(1-t)$ is allocated to household production. Market activity yields a marginal return (wage) of w_m for men and w_f for women, where I assume $w_m > w_f$.[23] Time allocations are a Nash equilibrium of a game in which each spouse decides his or her time allocation taking as given the time allocation of the other partner. (Results do not depend on the this specification. See Appendix B.1.1 for an example of the model with joint maximization.)

The welfare of a married individual consists of utility from consumption and utility from

[20] p_{Et} is defined in equation (6) below. How λ_{Et} is endogenously determined is discussed in Section 3.4.

[21] Similar effects may exist for girls as well: girls who grew up in male-breadwinner households may be more traditional than those who grew up in dual-earner households. For example, Olivetti and Patacchini (2012) study how women's working behavior is influenced by the working status of their mothers and their childhood friends' mothers using the National Longitudinal Survey of Adolescent Health. However, when economic growth creates opportunities for girls that did not exist for their mothers, girls are no longer constrained to traditional roles. Thus, given the time frame of my model—the past century during which women's wages increased greatly—the intergenerational transmission plays a much smaller role (on net) for girls than for boys. Section 4.1 presents supportive evidence (see footnote 38).

[22] I do not take a stance on the specific mechanism as I do not attempt to distinguish between them in my empirical work.

[23] When w_f is more than w_m, the wife works full-time whereas the husband works part-time ($t_f = 1, t_m = 1 - \frac{2\beta}{w_m}$). When w_f becomes sufficiently higher, ν_f intersects with V_{fM} (see Figure 5). After that point, an educated woman would choose not to marry even the modern type because the gain from consuming her income all by herself becomes larger than the gain from having a husband doing housework. In all countries, however, women's wages are still lower than men's, and hence I abstract from this case.

household public goods. Consumption is derived from total household earnings, $w_m t_m + w_f t_f$, which is split equally between the couple. The household public good is a function of the total time invested in household production, $(1 - t_m) + (1 - t_f)$, and $\beta > 0$ is the value of the public good to each individual.

The utility function of a man m married to a woman f is:

$$V_m(w_m, w_f) = \max_{0 \leq t_m \leq 1} \frac{1}{2}(t_m w_m + t_f w_f) + \beta log((1 - t_m) + (1 - t_f)) \tag{2}$$

where he takes t_f as given. Men's utility function depends only on wages.

On the other hand, the utility function of a married woman f also differs by husband's type $j = M, T$:

$$V_{fj}(w_m, w_f) = \max_{0 \leq t_f \leq 1} \frac{1}{2}(t_m w_m + t_f w_f) + \beta log((1 - t_m) + (1 - t_f)) - (\alpha_0 + \alpha_1(t_f))I_{j=T} \tag{3}$$

where $I_{j=T}$ is an indicator for whether husband is traditional type.

A married woman incurs a direct disutility of $\alpha_1(t_f)$, which is an increasing function of t_f, and a fixed amount of α_0 if her husband is traditional.[24] For analytical purposes, let $\alpha_1(t_f)$ be an indicator function: $\alpha_1 > 0$ when $t_f > 0$ and $\alpha_1 = 0$ when $t_f = 0$. Emotional gain from marriage may be reduced when the husband and in-laws are traditional, due to increased marital tensions, pressure to take better care of family members or to quit her job, or domestic violence.[25]

Note that the share $\frac{1}{2}$ is not affected by male type. That is, a traditional husband does not "steal" more from his wife than a modern husband, and hence there is financial benefit from marriage regardless of the husband's type. This is a conservative assumption; if the share also depends on the husband's type such that women married to traditional men get less than half, this would make traditional men even less attractive as partners (see footnote 18). Men's productivity at home is also assumed to be the same. The willingness to help may differ (and hence be incorporated in the disutility term), but it is unlikely that there are fundamental differences across men in their ability to do housework.

The first order conditions of equations (2) and (3) when the husband is a modern type yield:

$$\begin{cases} 2 - t_m - t_f = \frac{2\beta}{w_m} \\ 2 - t_m - t_f = \frac{2\beta}{w_f} \end{cases}$$

respectively. Because $w_m \neq w_f$, at least one of the agents must be at a corner solution.

[24] See Appendix B.1.1 for a discussion on how the model changes when the disutility term is only in the men's utility function.

[25] Refer to Section 2 to see cross-country variation in responses to stylized gender role questions. Research on the relationship between husbands' gender attitudes and the quality of marital relations provide further evidence. See for example, Hochschild (1989), Min (2001), and Rubin (1983).

There are two possible cases: (i) when $w_f \leq 2\beta$, $t_m = 1$ and $t_f = 0$, (ii) when $w_f > 2\beta$, $t_m = 1$ and $t_f = 1 - \frac{2\beta}{w_f}$. It is always optimal for married men to work full-time regardless of women's wages because $w_m > w_f$. A married woman becomes a housewife in case (i) but works part-time in case (ii).[26] Henceforth, I assume for clarity that uneducated women's wages $w_U \leq 2\beta$ and educated women's wages $2\beta < w_E < w_m$.

An individual's utility when single is defined analogously.[27]

$$\nu_i = \max_{0 \leq t_i \leq 1} w_i t_i + \beta log(1 - t_i) \tag{4}$$

The optimal time allocation is $t_i = 0$ when $w_i \leq \beta$ and $t_i = 1 - \frac{\beta}{w_i}$ when $w_i > \beta$. I assume that $V_m(w_m, w_U) \geq \nu_m$ so that men prefer to marry a housewife than to remain single (i.e., household production is valued).

Figure 5 characterizes a woman's utility as a function of her wage. Utility in marriage does not change with regards to a woman's wage when $w_f \leq 2\beta$ because she does not work in equilibrium. Note that because of $\alpha_1(t_f)$, a woman married to a traditional husband starts to work at a wage higher than 2β.[28] I denote this threshold wage as $\underline{w}_E$.

3.3 Marriage Decision

Matching is done as a one-period random search in which the probability of meeting another individual (of a different sex) of type j is given by the fraction of type j in the population.[29] Hence the probability that a woman is matched to a modern type is λ_M and the probability that she is matched with a traditional type is $1 - \lambda_M$. Individuals decide whether to stay in a match (that is, marry) and obtain utility V_{ij} as in equations (2) and (3) or to remain single and obtain utility ν_i as in equation (4). An individual i chooses to marry j if and only

[26] Outcomes are not assumed to be Pareto efficient ex-ante. Case (i) turns out to be Pareto efficient but (ii) is not when w_f is high enough to allow an educated woman to reject a traditional man. A Pareto improvement is then possible if the traditional man offers her a "bribe" to compensate her for the disutility she incurs from marrying him. Whether this can be a binding contract is highly questionable, however. The contract would require the husband to allow his wife to consume more than half the total income, and this would not be time-consistent if the traditional man could renege once the educated woman is married to him (and there is a non-trivial cost of divorce).

[27] Alternatively, I can assume that the value of household production is smaller for unmarried agents (i.e. smaller than β) if for instance, children are the main source of utility in household public goods and unmarried agents do not have children. This shifts the ν_i curve to the left in Figure 5, but all qualitative results remain unchanged. I keep the same β as in equations (2) and (3) to keep the algebra as simple as possible.

[28] α_0 is a level effect, and hence does not affect the threshold wage itself.

[29] Allowing individuals who are unmarried after the first round to redraw does not make any difference in the fraction and type of men and women who remain single, because only educated women and traditional men would remain. A directed search model would yield a higher fraction of married agents in the population, because modern men prefer educated women to uneducated women (V_m increases in w_f). However, a directed search model would require all women to correctly anticipate ex-ante what fraction of her contemporaries would choose to become educated.

if $V_{ij} \geq \nu_i$ holds.

$V_m(w_m, w_U) \geq \nu_m$ implies that men marry educated women as well as uneducated women, since V_m increases in w_f. A woman's marriage decision depends on the type of man she is matched to and her wage. If matched to a modern type, she chooses to marry. But if matched to a traditional type, she may prefer to remain single when her wage is sufficiently high. Given the disutility term, $\nu_f > V_{fT}$ is possible as wages rise because the marginal return from one's wage is higher when it is not shared with a spouse.

Denote the wage at which ν_f intersects with V_{fT} as $\widetilde{w}_E$ (see Figure 5). Depending on the relative size of α_0 and α_1, I then get the following relationship between $\underline{w}_E$, $\widetilde{w}_E$, and w_m:

Proposition 1.

$$\beta log2 < \alpha_0 + \alpha_1 < \frac{1}{2}(w_m - \underline{w}_E) + \beta log2 \tag{5}$$

When α_0 and α_1 satisfy equation (5), $\underline{w}_E < \widetilde{w}_E < w_m$. When they are larger, $\widetilde{w}_E < \underline{w}_E < w_m$. When they are smaller, $\underline{w}_E < w_m < \widetilde{w}_E$.

(The proof for this and all other propositions can be found in Appendix B.2.)

In words, if the disutility from having a traditional husband is too large, all educated women will decide to stay single when matched to traditional men. On the other hand, if the disutility is small, then all women will choose to marry even when they are matched to traditional men. In the intermediate case where α_0 and α_1 satisfy equation (5), an educated woman's marriage decision changes as her outside option improves. I focus on this last, non-trivial case. Assume that equation (5) holds and that $\alpha_0 \leq \beta log2$, so that α_1 is strictly larger than zero.

An implication of this search model is that when $w_E < \widetilde{w}_E$, women's marriage probabilities are invariant to the fraction of modern men in the marriage market because all women marry. Thus, uneducated women always marry. When $w_E \geq \widetilde{w}_E$, however, educated women matched to traditional types do not marry because $\nu_f > V_{fT}$. An educated woman with a high enough wage need not tolerate a traditional husband for the sake of his income.

Therefore, the expected marriage probability p_i of uneducated (U) and educated (E) women can be expressed as in equation (6), given that educated women randomly draw wages from $W(.)$ with support $(2\beta, w_m)$.[30]

$$\begin{cases} p_U(\lambda_M) = 1 \\ p_E(\lambda_M) = \int_{2\beta}^{\widetilde{w}_E} 1 dW + \int_{\widetilde{w}_E}^{w_m} \lambda_M dW \end{cases} \tag{6}$$

Consequently, a woman's expected utility conditional upon her educational attainment

[30]See Appendix B.1.2 for a discussion on how wages may instead be proportionate to the effort exerted such that a greater e generates a better wage distribution.

can be expressed as:

$$\begin{cases} V_U(\lambda_M) = \lambda_M V_{UM} + (1-\lambda_M)V_{UT} \\ V_E(\lambda_M) = \int_{2\beta}^{\widetilde{w}_E}(\lambda_M V_{EM} + (1-\lambda_M)V_{ET})dW + \int_{\widetilde{w}_E}^{w_m}(\lambda_M V_{EM} + (1-\lambda_M)\nu_f)dW \end{cases} \tag{7}$$

where V_{fj} and ν_f are as defined in equations (3) and (4).

3.4 Education Decision

I assume that each woman faces an idiosyncratic effort cost e of becoming educated, where e is an iid random draw from a continuous cumulative distribution function $G(.)$. Let

$$\widehat{e}(\lambda_M) \equiv V_E(\lambda_M) - V_U(\lambda_M) \tag{8}$$

be the expected utility differential between an educated and uneducated woman given the fraction of modern men, λ_M. Because wages are exogenous, $\widehat{e}(\lambda_M)$ is independent of the fraction of women who decide to become educated.[31]

$\widehat{e}(\lambda_M)$ has the following properties:

Proposition 2. *$\widehat{e}(\lambda_M)$ is an increasing function of λ_M, and $\widehat{e}(\lambda_M) \geq 0$ always holds.*

Since all women with effort cost $e \leq \widehat{e}(\lambda_M)$ decide to invest in education, the equilibrium $\lambda_E(\lambda_M)$—fraction of educated women—at any point in time is:

$$\lambda_E(\lambda_M) = G(\widehat{e}(\lambda_M)) \tag{9}$$

It follows directly from Proposition 2 that $\lambda_E(\lambda_M)$ is also a continuous, increasing function of λ_M on $[0, 1)$. $\lambda_E = 1$ (and therefore $\lambda_M = 1$) is ruled out, because e can be unboundedly large. In words, more women find it worthwhile to invest in education when there is a larger fraction of modern men because marriage prospects are better. But it is never the case that all women become educated because there are always a few whose cost of investing in education is very high.

3.5 Shock to Women's Wages and the Gold Miss Phenomenon

There are equal numbers of men and women in the society. Let the number of educated women at period t be denoted as F_{Et}:

$$F_{Et} \equiv \lambda_{Et}(\lambda_{Mt})F_t \tag{10}$$

[31] I abstract from general equilibrium effects on wages.

where F_t is the total number of women at t. The conditional probability of being unmarried when educated (being a Gold Miss), is simply $1 - p_E(\lambda_{Mt})$, where $p_E(\lambda_{Mt})$ is the marriage probability of educated women as defined in equation (6).

$W_t(.)$ is the continuous cumulative distribution function of educated women's wages in generation t over support $(2\beta, w_m)$. The following comparative statics can be made with regards to contemporaneous wages:

Proposition 3. *Given $W_{t-1}(.)$ and λ_{Mt-1}, if the distribution $W_{t1}(.)$ first-order stochastically dominates $W_{t2}(.)$, $F_{Et1} \geq F_{Et2}$.*

Proposition 4. *Given $W_{t-1}(.)$ and λ_{Mt-1}, educated women's marriage probability is an increasing function of $W_t(\widetilde{w}_E)$. Hence if the distribution $W_{t1}(.)$ first-order stochastically dominates $W_{t2}(.)$, $p_{Et1} \leq p_{Et2}$.*

That is, both the number of educated women and the probability that they remain unmarried are increasing in educated women's current wages. Proposition 3 is straightforward; more women are incentivized to invest in education when the returns to education are greater. Proposition 4 results because women with wages higher than $\widetilde{w}_E$ can afford to stay single when matched to traditional men.[32]

More important, however, is whether the probability of becoming a Gold Miss increases or decreases as wages rise *over time*, i.e. $p_{Et} - p_{Et-1}$.[33]

Proposition 5. *Suppose $W_t(.)$ first-order stochastically dominates $W_{t-1}(.)$ at all t. The decrease in p_E from $t-1$ to t is larger when (i) the drop in $W(\widetilde{w}_E)$ from $t-1$ to t is larger and (ii) the shift in $W(.)$ from $t-2$ to $t-1$ is smaller.*

That is, the Gold Miss phenomenon is more likely to arise in economies where there was a large, one-time shock to women's wages than in those that had a more gradual wage growth.

To understand why this is so, notice that wage increase affects p_E in two opposite directions. First, there is the contemporaneous effect: higher wages allow educated women to remain single when matched to traditional type and thus *lowers* marriage probability (Proposition 4). On the other hand, more women have an incentive to become educated when wages are high (Proposition 3) and this generates a larger fraction of modern males in the next generation. This intergenerational effect *raises* educated women's marriage probability by increasing the pool of marriageable men. The second effect, unlike the first, is lagged.

[32]Comparative statistics of Proposition 4 cannot be summarized with just the mean of $W(.)$. With first-order stochastic dominance, the mean increases with time. However, in the perverse case of the distribution changing without affecting $W(\widetilde{w}_E)$, an educated woman's marriage probability would remain constant regardless of the change in means (since all women with wages below $\widetilde{w}_E$ get married). In other words, growth in women's wages "on average" is not a sufficient condition for a decrease in p_E.

[33]Since uneducated women always marry, $p_{Ut} - p_{Ut-1} = 0$.

Condition (i) in Proposition 5 enlarges the first effect whereas condition (ii) curtails the second, resulting in the Gold Miss phenomenon. But if either of the conditions fail to hold, the two opposing effects come into play and p_{Et} may fall only slightly relative to p_{Et-1}, or may even increase.

In sum, the Gold Miss phenomenon should be best observed when there is a shock to women's wages in a country with a large fraction of traditional men. The key observation is that the results do not depend on societies being endowed with different types of men. Even if all countries had equally traditional men at $t = 1$ and the same wage level at $t = T$, mismatch in the marriage market would be a function of how rapidly the economy grew *between* $t = 1$ and $t = T$. Therefore, similarly developed countries at $t = T$ can have very different gender norms, which in turn dictates the variation in the degree of mismatch we observe in the marriage market.

Finally, it is worth noting that this path dependency feature may result in prolonged repercussions, well beyond the arising of the Gold Miss phenomenon. Countries may become "stuck" in the Gold Miss equilibrium because as long as the Gold Misses do not have children, they cannot contribute to producing a new cohort of modern males. But if the fraction of modern men depends on the fraction of *all* educated women in the previous cohort (regardless of marital status), then the fraction of modern men would increase greatly after the Gold Miss generation.

4 Evidence on the Effect of Cultural Transmission on the Gold Miss Phenomenon

I focus my empirical exploration of the model on four testable implications. First, men who grew up around highly educated women are less traditional than those who grew up around less educated women. Second, husband's type affects household time allocation; a woman is more likely to work in the labor market when her husband is a modern type. Third, women marry less traditional men (rather than traditional) when they are available. Fourth (and as a consequence of the prior points), the Gold Miss phenomenon is less severe when there is a larger fraction of modern men in the marriage market.

The ideal way to test these predictions would be to exogenously vary wage growth paths or the composition of male types within an initially traditional country and then see how the marriage market unfolds generations later. Because this is not feasible, I use three different datasets—the Japanese General Social Survey, the U.S. Census and the American Community Survey, and the American Time Use Survey—to test the four elements above.

4.1 Gender Attitudes and Marriage Patterns in Japan

I first analyze the Japanese General Social Survey (JGSS) to evaluate how a mother's education and employment affect her son's gender attitudes and marriage patterns in one of the Gold Miss countries—Japan.

4.1.1 Data

The JGSS is designed to solicit political, sociological, and economic information from men and women living in Japan and has been conducted seven times during the 2000s.[34] I pool these years for the analyses. The sample size is about 3,500 per year. Observations are always weighted to make the sample representative of the Japanese population.[35] Respondents younger than 25 or still attending school are excluded in order to obtain more accurate data on final education.

Appendix Table A1 contains descriptive statistics of the key variables. Only 3 percent of the respondents have college graduate mothers, because as mentioned in Section 2, not until the education reform after World War II could women attend college and even then many attended junior (two-year) colleges.

4.1.2 Results

My model rests on the notion that gender norms are subject to change and that men's views of gender roles are influenced by their mothers. I investigate this using individual's responses to five questions in the JGSS specifically designed to capture gender attitudes.

Respondents are asked whether they agree or disagree with the following statements: "If a husband has sufficient income, it is better for his wife not to have a job," "Men should cook and look after themselves," "A husband's job is to earn money; a wife's job is to look after the home and family," "A preschool child is likely to suffer if his/her mother works," and "It is more important for a wife to help her husband's career than to have one herself." An individual can be defined as less traditional if he/she agrees with the second statement, and disagrees with the other statements.

Figure 6 depicts the trend of the responses to these five statements across birth cohorts. The "less traditional index" ranges from 0 to 5: it equals 5 if the individual responded less traditionally to all five questions (whether that corresponds to agreeing or disagreeing depends on the specific statement). Women are less traditional than men and the gap is larger in recent cohorts. Also, there has been a significant evolution of beliefs for both men and women over time. Those who were born after 1960 responded less traditionally to at least one or two more statements compared with those born in the 1920s.

[34] 2000, 2001, 2002, 2003, 2005, 2006, and 2008.

[35] See Appendix A.3 for how the weights are constructed.

To investigate whether the mother-to-son transmission exists, I estimate the following linear probability model:

$$Y_{ist} = \beta_0 + \beta_1 X_{ist} + \beta_2 MomLFP_{ist} + \beta_3 MomColl_{ist} + \gamma_t + \delta_s + \varepsilon_{ist} \tag{11}$$

where the dependent variable Y_{ist} is an indicator variable that equals 1 if the response to the specific question (listed above) is less traditional for a man i who lives in region s and belongs to cohort t. $MomLFP_{ist}$ equals 1 if his mother had a paying job when he was about 15 years old, and $MomColl_{ist}$ equals 1 if his mother is a college graduate.[36] X_{ist} represents a set of demographic controls such as respondent's age, education, and income. In addition to regional and urban dummies δ_s, I include cohort fixed effects γ_t to take into account the time trend observed in Figure 6.[37]

Table 1 contains the estimation results. The coefficients on having had a working and college graduate mother are always positive, and are statistically significant in cols. 1, 3, and 4. The probability that a man disagrees with the statements "If a husband has sufficient income, it is better for his wife not to have a job," "A husband's job is to earn money; a wife's job is to look after the home and family" and "A preschool child is likely to suffer if his/her mother works" increases by about 5 percentage points if his mother worked relative to if his mother did not work when he was young and by more than 10 percentage points if his mother is a college graduate. These are comparable in magnitude to the marginal effect of the respondent himself being college graduate. Father's educational attainment, on the other hand, has no statistically significant effect. The results are robust to restricting the sample to currently married men.[38]

If men who had working and/or college graduate mothers are indeed less traditional, are they more likely to be married than men who had housewife mothers? And are their wives more likely to work after marriage?

To address the first question, I look at the correlation between a mother's background and her son's marriage probability. Table 2 shows that there is a small but positive relationship between a mother's LFP and her son's marriage probability (col. 1). To reduce the bias from potential correlations between a mother's work status and her son's ability, and since the

[36]The JGSS asks "When you were about 15 years old, did your mother have any paying job? If so, what did she do?" $MomLFP_{ist}$ is zero for those who answered "She was not working." Respondents who "Don't know" or did not have a mother at that time are excluded. $MomColl_{ist}$ equals 1 for four-year colleges (not junior college or college of technology).

[37]There are 47 prefectures in Japan, which are governmental bodies larger than cities, towns, and villages. The prefectures are grouped into six regions ("blocks") in the JGSS. Urban is a set of three dummies for the size of municipality—largest cities, other cities, and town/village. Largest cities are the "Cabinet-Order designated cities" that have more than 500,000 people.

[38]When I replicate this analysis for *female* respondents, I find that both mother's LFP and mother being a college graduate do not have statistically significant effects on women's gender attitudes. Consistent with the model's assumption, the intergenerational transmission of gender attitudes matters more for men than women.

model focuses on the case where men's wages are higher than women's, I run the regression for just the college graduate men in col. 2. I find that mother's LFP has a larger positive effect than when all men are considered. As for mother's educational attainment, the coefficient is positive but statistically insignificant. Thus, a man's likelihood of marriage is higher if his mother worked or is a college graduate.

To address the second question, I estimate equation (11) with wife's current labor force participation (measured by whether she had any paying job in the last week) as the dependent variable. Table 3 contains the results. Having a college graduate mother does not have a statistically significant effect on wife's probability of working. But a man having had a working mother when he was young raises the probability that his wife works by about 6 percentage points. When the sample is restricted to college graduate men, the effect is 7.2 percentage points. This is more than a 10 percent increase since the mean of married women's LFP is about 50 percent.

Note that region, urban, and rural at age 15 dummies are included to control for regional variation; places with female-dominated industries may bias the mere chance that both mother and wife are employed. Wife's LFP is negatively correlated with husband's education, income, and the total number of children in the household. It is positively correlated with herself being college graduate. Using wife's usual hours worked per week instead of her LFP as the dependent variable yields similar results.[39]

Altogether, these results suggest that a mother's work experience and educational attainment affect her son's gender attitudes and marriage. Consistent with the model's assumption on intergenerational transmission, men who had working and college graduate mothers are more likely to have egalitarian gender attitudes. The probability that a man ever marries and that he has a working wife also increases with his mother's LFP and education.

4.2 Time Use of Married Immigrants in the U.S.

We have just seen that Asian men are tradition-bound but are less so when their mothers are more educated and work more outside the home. The supply of modern men in Asia is therefore limited. What happens when educated Asian women live in areas with more modern men? In this section, I explore time use of married immigrants in the U.S. to see whether a husband's type—as proxied by his country of origin and U.S. nativity—affect his and his wife's time spent on household chores.

[39]The coefficient on mother's LFP is 3.4 hours per week for all men and 4.1 hours per week when the sample is restricted to college graduate men. They are both statistically significant at the 1 percent level.

4.2.1 Data

I use the 2003–2011 waves of the American Time Use Survey (ATUS) to explore the time spent by respondents (and their household members) on both market and non-market activities. Because the survey is also linked to the Current Population Survey, which contains information on father's and mother's birthplace for all respondents, I am able to identify an individual's country of origin. Because the sample size of those from Gold Miss countries (Hong Kong, Japan, Korea, Taiwan, and Singapore) is small, I expand my analyses to those from "traditional" and "less traditional" countries in general. (Results for Gold Miss countries only are reported in the Appendix.)

I use female labor force participation (FLFP) rates in father's birthplace to divide countries into traditional and less traditional groups.[40] The United Nations (UN) provides data (from the International Labor Organization) on women's share of labor force in 187 countries starting from 1985. To focus on adult women's LFP and to obtain statistics for as many countries as possible, I use the FLFP rate of the 25–34 age group. I also use the oldest data available, 1985, to better reflect the gender norms that immigrants were exposed to before migrating to the U.S.

I define high (low) FLFP countries as *countries where women's LFP rates in 1985 were higher (lower) than that of the U.S.*—70.9 percent. U.S. is used as the standard since the shift in gender norms that immigrants experience derives from the contrast between their country of origin and the U.S. A total of 121 countries in the UN data are matched to father's birthplace in the ATUS sample, of which 42 countries are high FLFP and 79 are low FLFP. (See Appendix Figure A2 for a map of the countries by category.)

For all analyses in this section, only married couples with spouse present are considered since couples who are currently separated or divorced do not face the same constraints in determining time allocation as couples living together. Couples with either respondent or spouse under age 25 are excluded. In comparing across generations, I distinguish between foreign born, second generation, and third and higher generations. All foreign born immigrants are categorized as foreign born regardless of their age at migration.[41] Second generation is U.S. born respondents whose fathers are foreign born. Third and higher generations are U.S. born respondents whose fathers are also U.S. born.

Appendix Table A2 contains the summary statistics of my sample. Immigrants with

[40] I can alternatively use mother's birthplace and the results are similar (95 percent of respondents have parents born in the same country). FLFP is commonly used in the political economy literature as an indicator of a country's family culture and women's economic status. See for example, Alesina and Giuliano (2010) and Fernandez and Fogli (2009). For my purposes, married women's LFP rates would be ideal, but they are not available in cross-country datasets.

[41] There are no respondents who are foreign born yet with a U.S. born father in the sample, reducing the possibility of bias from adoptees. I also do not exclude those who have migrated to the U.S. as adults because unlike education and marriage decisions in Section 4.3 below, time use at home within married couples is an everyday practice, and thus is not contingent on the decisions made back home.

low FLFP origin compose more than 80 percent of foreign born and 70 percent of second generation men and women. By definition, the fraction is zero for third and higher generations. Among those with low FLFP origins, about 40 percent of them are from Mexico in the foreign born group; hence, I include a dummy for Mexican origin in all my analyses.

4.2.2 Results

There are several ways to group non-market activities. I have chosen to use "core non-market work" in Guryan, Hurst and Kearney (2008), which includes activities such as food preparation, indoor cleaning, and washing/drying clothes. Time spent on shopping, and other home production such as home maintenance, outdoor cleaning, vehicle repair, gardening, and pet care are excluded, as well as time spent on child care, medical care, education, and restaurant meals. Throughout, I refer to "core non-market work" as housework.[42]

Figure 7 summarizes the time spent on housework by sex, generation, and country of origin. Married men spend on average five hours or less on housework and married women's hours are about three times longer. For women from high FLFP countries, hours stay roughly constant across generations. For women from low FLFP countries, there is a clear reduction across generations: the mean of housework time falls by about six hours—from 21.8 hours per week among the foreign born to 15.6 hours per week among the second generation. Variation among married men is much smaller: there is less than an hour increase from foreign born to U.S. born among those from low FLFP countries.

According to the model, men from countries where most women work (high FLFP origin or U.S. born) are more likely to be the modern type than those who grew up in countries where most women are housewives (foreign born from low FLFP countries). Since Figure 7 does not control for systematic differences that may exist between different groups, I estimate the following equation to investigate the effect of cultural background on men's housework hours:

$$Y_{ist} = \beta_0 + \beta_1 X_{ist} + \beta_2 U.S.born_{ist} + \beta_3 third_{ist} + \gamma_t + \delta_s + \varepsilon_{ist} \tag{12}$$

where the X_{ist} are demographic controls such as age, education, usual work hours, the number of children in household, the age of the youngest child in household, and race, and year (γ_t) and state (δ_s) fixed effects are included.[43] The variable $U.S.born_{ist}$ equals 1 if the respondent is U.S. born and 0 if foreign born. $third_{ist}$ equals 1 if respondent is third or higher generation and equals 0 otherwise; hence, together with $U.S.born_{ist}$, I am able to distinguish between foreign born, second, and third or higher generations. Standard errors

[42] All findings are robust to using a broader definition that includes other home production activities, such as "total non-market work" in Guryan, Hurst and Kearney (2008).

[43] Usual work hours are only available for individuals who are employed. I recode the variable to zero for those currently unemployed. Individuals who responded "hours vary" are excluded from the analyses. Race has 21 categories and includes multiple-race in addition to all major single race classifications.

are clustered by father's birthplace.

Table 4 shows the OLS regression results, separately for men from low FLFP countries and high FLFP countries. For men from low FLFP countries (cols. 1 to 3), the key variable of interest is U.S. born. (This refers strictly to second generation since, by definition, there is no third or higher generation with low FLFP origin.) The coefficient is positive and statistically significant. Taking into account working hours and family characteristics, a U.S. born man with a low FLFP origin spends about 0.8 more hours on housework than a foreign born one, a non-trivial difference considering that the mean housework time for men is 4.5 hours per week.

Unsurprisingly, being U.S. born matters less for men from high FLFP countries (cols. 4 to 6). The marginal effect of being U.S. born and the additional effect of being third or higher generation are both statistically insignificant when all the controls are included.[44]

To rule out the potential concern that the results are driven by ethnic composition effects, I repeat the analysis above for men from Gold Miss countries only. Of course, the Gold Miss countries—Hong Kong, Japan, Korea, Singapore, and Taiwan—are all in the low FLFP category. Table 5 presents the estimates from the OLS regression. Despite the small sample size, the coefficient on U.S. born is large and highly significant. Relative to foreign born, Asian American men spend about four hours more on housework when the couple's demographics and working hours are considered (cols. 1 and 2) and 2.5 hours more when the number and age of children are considered as well (col. 3).

Thus, modern husbands—U.S. born and/or from high FLFP countries—spend more time on housework than traditional husbands, taking into account couple's demographics, working hours, and children. However, the difference is much smaller than the variation in women's housework hours observed in Figure 7. In fact, given that men earn higher wages than women in most families, the important distinction between modern and traditional type males may not be in their own housework hours but in how much they desire the housework to be done by their wives. The model predicts that a woman married to a traditional husband does more housework than a woman married to a modern one, ceteris paribus.

I investigate the effect of husband's cultural background on wife's housework hours, and I focus on women from low FLFP countries.[45] The regression is similar to equation (12)

[44]These results are also robust to a more general definition of traditionality. In Appendix Table A3, I use the actual FLFP rate in the respondent's father's birthplace instead of the dichotomous distinction of high and low FLFP origins. Consistent with the findings above, the marginal effect of being U.S. born and the marginal effect of the FLFP rate are both positive while the interaction between FLFP rate in father's birthplace and U.S. born is negative. That is, the difference in housework time between U.S. born and foreign born is smaller among men from countries with higher FLFP rates.

[45]Women from high FLFP countries are rarely married to traditional men—both by origin and U.S. nativity standards. Among married women with high FLFP origins, only 4.7 percent have husbands with low FLFP origins and only 4.6 percent have husbands who are foreign born. There is variation in husband's background among married women with low FLFP origins, however. 27 percent of them have husbands with high FLFP origins and 37 percent of them have husbands who are U.S. born.

but with husband's country of origin and generation since migrating to the U.S. as the key covariates, and standard errors clustered by husband's father's birthplace.

Table 6 contains the estimation results. Col. 1 shows that having a husband from a low FLFP country increases a woman's housework time by about three hours per week compared with having a husband from a high FLFP country. When only U.S. nativity is considered, col. 2 indicates that husbands who are third generation show the opposite effect: they lower wives' housework time by three hours. When both husband's country of origin and U.S. nativity are included as covariates in col. 3, husband's origin remains large and significant (the magnitude is larger than the effect from the woman herself being U.S. born) whereas the coefficient on husband's U.S. nativity loses significance.

In Table 7, I repeat the exercise above with just the women from Gold Miss countries. The sign of the coefficients on husband's origin and U.S. nativity are the same as in Table 6 and the size of the coefficients are even larger: country of origin and husband being third generation have marginal effects of about six hours per week when considered separately (cols. 1 and 2). When both are included as covariates in col. 3, the average housework time of Asian women married to third generation men is about 8.9 hours less than those married to foreign born or second generation men. The magnitude translates into more than a 50 percent drop in married women's housework time.

These results are consistent with the prediction that variation in housework hours of married women can be partly attributed to husbands' cultural backgrounds. The type of the men matters not so much because men do the housework but because they do not mind their wives' doing less and outsourcing more.

Furthermore, the findings above imply that cross-country differences in family-friendly environment or substitutability between household production and market goods cannot be the main determinant of the Gold Miss phenomenon. As mentioned in Section 2, not only are the relative prices of outsourcing housework in the U.S. and East Asia similar, but as shown here, there is a wide cultural variation in household time allocations even among those living in the same country.

4.3 Marriage Patterns of Koreans and Japanese in the U.S.

My research and others suggest that immigrants are culturally similar to those in their home countries and U.S. born men are less traditional than Asian born men.[46] Thus, immigration from the Gold Miss countries to the U.S. can demonstrate how the marriage market equilibrium would change when more modern males become available in Asia. I use the U.S. census data to examine whether the Gold Miss phenomenon similarly exists among Koreans and Japanese in the U.S., and if not, whom the women are marrying in the U.S.

[46]See footnote 8 for references on U.S. immigrants' cultural and economic assimilation.

4.3.1 Data

I use the 1980, 1990, 2000 Census and the 2001 to 2010 American Community Survey (ACS) IPUMS files.[47] A respondent is defined as Korean or Japanese if categorized as "Korean" or "Japanese" in the single race variable.[48] (Hong Kong, Taiwan, or Singapore is not recognized as single race categories. They are grouped as "Other Asian" or "Chinese.") Individuals younger than 25 or still attending school are excluded.

I distinguish between first and higher generations of immigrants. Because immigrants may have chosen to come to the U.S. after completing their final education in their home countries or getting married, bringing their spouses with them, I only use respondents who immigrated to the U.S. when they were younger than 18 years old. I also exclude respondents who migrated before three years old to limit the bias from including Korean and Japanese adoptees.[49] Foreign born in this section refers to *immigrants who came to the U.S. between ages 3 and 17*. Second and higher generations are grouped as U.S. born.[50]

Appendix Table A4 reports the descriptive statistics of my sample. Foreign born are comprised of fewer Japanese because the wave of immigration from Korea has been more recent. Hence, I control for respondent's ethnicity in all my analyses.

4.3.2 Results

Before moving to the main empirical tests, I examine the educational attainment of Koreans and Japanese in the U.S. Figure 8 plots the fraction college graduate by sex, nativity, and cohort. During the past 50 years, the percentage of four-year college graduates among Korean and Japanese women increased from less than 20 percent to more than 60 percent. Although there were more male college graduates in the early cohorts, the increase was more gradual

[47]The Census and the ACS are the only datasets that have sufficiently large sample size to study the Koreans and Japanese in the U.S.

[48]The Census and ACS collect parent's birthplace only for respondents who live with their parents at the time of the survey (less than 5 percent of the adult population). Single race is assigned according to respondent's self-reported race in the survey and is comparable across all years and is available for all respondents (including those with multiple-race). Individuals with multiple-race are assigned to the single race category deemed most likely. However, multiple-race is extremely rare among Koreans and Japanese: 99 percent of Koreans and 98 percent of Japanese self-reported themselves as "Korean" or "Japanese" in the detailed race question (and not "Korean and White" or "Japanese and White," for instance).

[49]See Appendix A.5 for how age at migration is calculated. Adoptees may be identified as Korean or Japanese in the Census despite having been brought up by American parents and not having any cultural connections to Korea or Japan. According to the Intercountry Adoption statistics from the U.S. Department of State, 99 percent of adoptees from Korea and Japan in 1999–2011 arrived in the U.S. when they were younger than three years old. The Holt International Children's Services data in Sacerdote (2007) also shows similar figures for Korean adoptees placed during 1964–1985: 91.4 percent of children arrived under the age of three.

[50]It is impossible to distinguish between these generations without information on parent's birthplace. Since the immigration wave from East Asia began in the 1960s (after the Immigration and Nationality Act Amendments of 1965), third or higher generations are expected to comprise a small fraction of my sample. Naturalized citizens are not categorized as U.S. born.

for men, resulting in a switch in the educational gender gap. The overall development across time is similar for the foreign born and the U.S. born, with levels reaching about 60 percent from the 1970s birth cohort for both men and women. Hence, the fraction college graduate is larger among Koreans and Japanese in the U.S. than among white Americans (less than 40 percent).

The Gold Miss phenomenon among Koreans and Japanese who immigrated to the U.S. may well be more severe because the sex ratio among college graduates in the U.S. is less in favor of women than in Korea and Japan, where there are more male than female college graduates (see Figure 2). However, Figure 9 shows that college graduate Koreans and Japanese are as likely to be married as the non-college graduates. For both sexes, the fraction married among college graduates relative to non-college graduates has been increasing across cohorts, and the difference switched from negative to positive for women. This contrasts starkly with the downward trend found in Asia and is instead similar to the trend observed among Americans overall (see Figure 4). The Gold Miss phenomenon does not hold in the U.S.

Because women's educational attainment, labor force participation, and wages increased decades earlier in the U.S. than in Asia, men who grew up in the U.S. have less traditional gender attitudes than those who grew up in Korea and Japan. College graduate women would then have greater options in the U.S. marriage market than in Korea or Japan.

This notion appears to have much validity. Among the college graduate and foreign born Koreans and Japanese (Table 8 Panels A and B, row 1), women are much more likely than men to have a spouse who is neither Korean nor Japanese. The gender gap is large: one third of these women married U.S. born who are not Korean or Japanese while only 16 percent of men did, and about half of the women married foreign born Korean or Japanese while more than 70 percent of men did.

The gender gap in spouse's ethnicity is smaller among the U.S. born Koreans and Japanese (Panels A and B, row 2). The incidence of having a foreign born Korean or Japanese spouse falls to 6 percent for women and 12.5 percent for men. The vast majority of both sexes marry U.S. born—89 percent of women and 81 percent of men—although men tend to marry Korean or Japanese Americans while women tend to marry Americans who do not identify themselves as Korean or Japanese (mostly white). The differential marriage pattern by respondent's sex and U.S. nativity are robust to including respondent's age, education, ethnicity, and state and cohort fixed effects (see Appendix Table A5).

Thus, my findings suggest that Korean and Japanese men and women have different preferences for their spouse's ethnicity and U.S. nativity. Korean and Japanese men (particularly foreign born) usually marry Korean or Japanese immigrants whereas Korean and Japanese women (even those who are foreign born) marry Americans.

To test whether women's inclination to marry out of their ethnic group can be explained

by the Korean and Japanese men being more traditional than American men, I exploit regional variation in the composition of the Korean and Japanese male population. That is, for each state-cohort cell (six decennial birth cohorts and 51 states, including the District of Columbia), I calculate the fraction foreign born among Korean and Japanese men—number of foreign born Korean and Japanese men divided by the total number of Korean and Japanese men. A larger share means that there are more foreign born than U.S. born among the Korean and Japanese men in respondent's state and cohort.[51]

The estimating equation is the following linear probability model:

$$Y_{ist} = \beta_0 + \beta_1 X_{ist} + \beta_2 fracfb_{st} + \beta_3 total_{st} + \gamma_t + \delta_s + \varepsilon_{ist} \tag{13}$$

where the dependent variable is an indicator variable that equals 1 if husband is not Korean or Japanese and 0 otherwise. The key covariates $fracfb_{st}$ and $total_{st}$ are, respectively, the fraction foreign born among Koreans and Japanese men and the total number of Koreans and Japanese men in the respondent's state s and cohort t.[52] The usual demographic controls are included. Cohort fixed effects absorb common time trends that may exist with regards to immigration from Asia or discrimination against interracial marriage. State fixed effects control for differences across states such as the type of industries and racial composition. Standard errors are clustered at the state-cohort level.

Table 9 presents the result of estimating equation (13) separately by education and U.S. nativity of Korean and Japanese women. The positive coefficient on fraction foreign born among Korean and Japanese men shows that the probability a Korean or Japanese woman marries out of her ethnic group increases when there are fewer U.S. born among the Korean and Japanese men in her state-cohort. Moreover, consistent with the model's assumption that the disutility from having a traditional husband is greater for educated women than for uneducated women, the coefficient is larger in magnitude for college women (cols. 1 and 2) than for non-college women (cols. 3 and 4).

The results are not driven by differences in the chance of meeting a Korean or Japanese of the opposite sex or the competition between Koreans and Japanese of the same sex in the marriage market; I control for both the total number of Korean and Japanese men and women in the respondent's state and cohort and also the fraction foreign born within the female population. Therefore, the findings imply a causal relationship between a Korean or Japanese woman's decision to marry outside her ethnic group and the composition of men in her own ethnic group.

Repeating the analysis for Korean and Japanese *men* shows that the fraction foreign born

[51] Pooling all state-cohort cells, the fraction foreign born among Korean and Japanese men ranges from 0 to 1 and has mean of 0.51 and standard deviation of 0.29. Hawaii and Idaho have low fraction foreign born whereas New Jersey and New York have high fraction foreign born among Korean and Japanese men.

[52] State here refers to the state of current residence. Note that state of birth cannot be used because of the foreign born group.

among the Korean and Japanese women in respondent's state and cohort does not have a statistically significant effect. That is, Korean and Japanese men's preference for Asian wives do not respond sensitively to the composition of the female population (see Appendix Table A6).

One potential concern with the interpretation that Korean and Japanese women marry American men because they are modern is that white men might marry Korean and Japanese women expecting them to be obedient housewives. Another is that Korean and Japanese women might marry Americans to "marry-up" in socioeconomic status.

To address the first concern, I examine Korean and Japanese women's LFP after marriage. Table 10 contains OLS estimates from regressing Korean and Japanese women's LFP on own and spouse's characteristics (including the husband's income) and the number of children in household. For foreign born Korean and Japanese women, having a husband who is not Korean or Japanese increases the probability of working by 9.3 percentage points. The coefficient on husband being U.S. born is statistically insignificant.[53] As for U.S. born Korean and Japanese women, both husband's nativity and ethnicity do not have statistically significant effects on women's LFP though positive in sign. Using alternative definitions of work status, such as usual hours worked per week, yields similar results.[54] Thus, it does not seem likely that Korean and Japanese women who are married to American men are very traditional.

To address the second concern, I look at the relationship between husband's ethnicity (and U.S. nativity) and his education level relative to his wife's.[55] Table 11 presents the estimates from regressing an indicator variable that equals 1 if the respondent's husband has higher educational attainment than herself (i.e., she is marrying-up). I run separate regressions for foreign born and U.S. born Korean and Japanese women. The hypothesis that an American husband has higher relative education can be rejected for both groups. Chen and Takeuchi (2011) similarly find using the National Latino and Asian American Survey that Asian women in the U.S. who marry non-Asians are not marrying-up in terms of education or occupation status.

In summary, female Korean and Japanese college graduates in the U.S. are as likely to be married as are non-college graduates. In terms of spouse's type, Korean and Japanese women in the U.S. are much more likely to marry Americans than their male peers, particularly when the fraction of first generation immigrants is large within the Korean and Japanese male population. Korean and Japanese women's LFP after marriage and their education

[53]This is because as seen in Table 8, almost all foreign born women either marry a foreign born Korean or Japanese or a U.S. born who is not Korean or Japanese, and hence the two covariates are collinear.

[54]When usual hours worked per week is the dependent variable, the coefficient on husband not being Korean or Japanese is 2.5 and statistically significant at the 10% level.

[55]Education is used as a proxy for socioeconomic status because it is highly predictive of potential earnings and is also available for all sample (including the non-working) unlike income or occupation data.

levels relative to their husbands' suggest that the observed marriage patterns are not driven by the selection of American men who want housewives or the marrying-up of Asian women.

5 Conclusion

The "East Asian tigers" transformed into developed economies in less than 50 years. Today, women's educational attainment and labor market performance in this region have become comparable to, or even surpassed those of other developed countries. In contrast to the U.S., however, marriage rates of college graduate women in Asia have become lower relative to that of non-college graduate women. The low marriage rates of college educated Asian women has been termed the "Gold Miss" phenomenon.

I argue that the Gold Miss phenomenon arises in traditional societies that underwent rapid growth in women's wages. Rapid improvement in women's economic status creates a gap between the women's role that men grew up observing and the role that the new generation of educated women choose to take. I test my hypothesis using data from Japan and the U.S. In Japan, I find that a mother's working status and educational attainment are positively correlated with her son's gender attitudes and his likelihood of having a working wife. In the U.S. time use data, I find that husbands from countries with low female labor force participation rates, like the Gold Miss countries, increase wives' housework burden. Finally, women from Korea and Japan—two major Gold Miss countries—have greater options in the U.S. marriage market because they can marry American men instead of Korean and Japanese men. Indeed, in the U.S., Korean and Japanese college women are as likely to be married as non-college women.

Overall, this paper provides an explanation for why the Gold Miss phenomenon arose in developed Asian countries and also identifies the driving forces behind the evolution of educated women's economic and household role.

A Data Appendix

A.1 Korean Data

The Korean Population Census is collected by the National Statistical Office every five years and are 2 percent samples of the population, excluding the institutionalized. Micro-data is available for years 1995, 2000, and 2005. The 2005 data does not distinguish between four-year colleges and less than four-year colleges, however, and hence I only use the 1995 and 2000 samples ($N = 1,756,493$). For the most recent cohorts, I use the Korean Economically Active Population Survey instead. It is collected monthly and covers individuals age 15 and older (both in and out of labor force) in Korea. I pool all months of 2012 ($N = 327,865$).

A.2 Hong Kong Data

The 2006 Hong Kong Population By-Census is collected by the Hong Kong Census and Statistics Department and is a 5 percent sample of the population ($N = 460,197$). Educational attainment is defined using the variable EDUCNH (highest level completed). The four groups corresponding to high school, junior college, college, and graduate school are: senior secondary, post-secondry (non-degree), post-secondary (degree), and graduate school. More specifically, senior secondary includes secondary forms 4 to 7; post-secondary (non-degree) includes various diploma courses and vocational training schools; post-secondary (degree) includes degree institutions; graduate level includes master degree, PhD, and other postgraduate courses.

A.3 JGSS

The JGSS has a variable WEIGHT to weight data for population estimates based on the Japanese Population Census. In the 2000–2005 datasets, this is produced by calculating the number of people which one respondent represents by taking into account sex (two categories), 10–year age group (six categories), region (six categories), and city or not (two categories). From 2006, the variable is produced by sex (two categories) and 10–year age groups (seven categories). In order to attach weights across survey years, I harmonize this variable so that weight is constructed from sex (two categories) and 10–year age group (six categories) for all years in my sample.

Income (SZINCOMX, SSSZINCM) reports the total annual income during the previous year (before taxes and other deductions) from main job. This is converted into 1999 yen using the Consumer Price Index adjustment factors. All top-coded values in each year are multiplied by 1.45.

In the 2008 survey, age is reported in intervals. I construct respondents' exact age by subtracting birth year (which is available across all years) from the year of the survey. Respondents under age 25 are excluded from the sample. However, birth year for spouse is not provided. Hence, I take the midpoint of each 10–year age group for the spouse. The intervals range from age group 20–29 to 90–99. Hence, spouses who are actually under age 25 may be included in the analyses.

To control for the number of children when analyzing married women's labor force participation, we need to know the number of children (under a certain age) who are currently living with the respondent. Total number of children (CCNUMTTL) variable in the JGSS, however, counts both those who left home or are deceased. Hence, I construct a variable

that counts the number of children under 19 living with the respondent by compiling the age of each child (CC01AGE, CC02AGE, etc.) as reported by the respondent. Because child's age is categorical data in 10–year age groups, I use 19 as the cut-off (instead of 18, as in other datasets).

A.4 ATUS

I weigh all observations using the person weight (WT06) to make the sample representative. Family income (FAMINCOME) includes the income of all members of the household who are 15 years of age or older. Income includes money from jobs, net income from business, pensions, dividends, interest, Social Security payments, and any other monetary income received by family members. This is the only earnings information available on the self-employed as well. It is based on categorical data; I calculate the midpoint of the categorical variable. When top-coded ($75,000 from January to September in 2003 and $150,000 thereafter), it is multiplied by a factor of 1.45.

Individuals whose father's birthplace (FBPL) is indicated as regions or continents, such as "Central America n.s.' and "Africa n.s.' are excluded from the analyses. For the countries that are named or grouped differently in the ATUS from the United Nations dataset, the following adjustments have been made (FBPL are assigned the LFP rate of the country in parenthesis): Czechoslovakia and Czech Republic (Czech Republic); Korea and South Korea (Republic of Korea); England, Scotland, Wales, United Kingdom, and United Kingdom n.s. (United Kingdom); Ireland and Northern Ireland (Ireland); Other USSR/Russia and USSR n.s. (Russian Federation).

A.5 U.S. Census and ACS

I weigh all observations using the IPUMS person weight (PERWT) to make the sample representative. Age at migration is calculated by subtracting the respondent's birthyear from the year of immigration variable. For cases when the year of immigration is given as intervals, I take the most conservative approach by using the last year in the bracket (to ensure that I do not include any immigrants who came to the U.S. when older than 17). Income (INCTOT) reports total pre-tax personal income or losses from all sources for the previous year. This is converted into 1999 dollars using the Consumer Price Index adjustment factors. All top-coded values in each year are multiplied by 1.45.

B Technical Appendix

B.1 Discussions

B.1.1 Disutility Term and Joint Maximization

Other things equal, assume that the disutility term is in men's utility function instead of women's. Then the utility of a married man of type M, T is:

$$\begin{cases} V_M(w_m, w_f) = \max_{0 \le t_m \le 1} \frac{1}{2}(t_m w_m + t_f w_f) + \beta log((1-t_m) + (1-t_f)) \\ V_T(w_m, w_f) = \max_{0 \le t_m \le 1} \frac{1}{2}(t_m w_m + t_f w_f) + \beta log((1-t_m) + (1-t_f)) - (\alpha_0 + \alpha_1(t_f)) \end{cases}$$

whereas a married woman's utility function is invariant to the type of husband.

$$V_f(w_m, w_f) = \max_{0 \leq t_f \leq 1} \frac{1}{2}(t_m w_m + t_f w_f) + \beta log((1 - t_m) + (1 - t_f))$$

Given $w_m > w_f$, a married man always works $t_m^* = 1$. Unlike in Section 3.2, a woman's optimal time allocation, t_f^*, now does not depend on the type of husband: if $w_f > 2\beta$, she spends $1 - \frac{2\beta}{w_f}$ of her time on market activities and if $w_f \leq 2\beta$, she stays at home.

Since t_f^* is increasing in w_f, and men's disutility is also increasing in t_f^*, there is a threshold wage w_f where V_T drops below ν_m.[56] Hence, Gold Misses arise when traditional men reject educated women with wages above this threshold. The expected utility from becoming educated ($V_E(\lambda_M)$) and the fraction of educated women (λ_E) *decrease* as women's wages rise over time.

Therefore, the model is not isomorphic to the case with the disutility term in men's utility function. In papers that study only married couples (and not whether to marry or not) or that do not focus on changes in women's wages over time (for example, Fernandez, Fogli and Olivetti (2004)) both setups may yield similar results.

Alternatively, the two cases can be isomorphic in a joint maximization framework. For example, let each married household maximize the following weighted average of husband's and wife's utility:

$$\max_{0 \leq t_m, t_f \leq 1} \theta U_m(c_m, h, t_m, t_f) + (1 - \theta) U_f(c_f, h, t_m, t_f) \tag{14}$$

where $0 < \theta < 1$, c_i is consumption, h is household public goods, and t_i is defined as before. (Unmarried agent's utility function is defined analogously.)

Assume that time spent on market activity enters directly into the utility function because the disutility from working is smaller than the disutility from doing household chores. That is, in addition to earning market wage w_i, self-fulfillment, working conditions, and other fringe benefits from a job are higher than from staying at home.[57]

Hence, some function of $t_i + \gamma t_j$ enters in the utility of agent i married to agent j, where $\gamma \leq 1$ is the relative weight on spouse's time spent on market activity. For simplicity, assume $\gamma = 0$ for all women and modern men. That is, apart from the utility gain from increase in household income, there need not be any additional utility gain from one's spouse working versus staying at home.

Traditional men, however, are characterized by a large negative γ. They get disutility from wife working. Thus, solving equation (14) given wages, a woman is more likely to be a housewife when her husband is traditional.

Furthermore, since the disutility from working is smaller than that from housework, a woman with a sufficiently high wage would choose to remain single when matched to a traditional man. When single, she can optimally outsource housework whereas when married to a traditional man, she has to do the less enjoyable housework due to her husband's disutility. Men always prefer to marry since with $w_m > w_f$, they always work in equilibrium.

[56] I abstract from the trivial case where the disutility is so small that everybody marries.

[57] Note that this does not imply that individuals enjoy working per se. In that case, wages would be negative.

B.1.2 Effort and Wage Distributions

Wages may be proportionate to the effort exerted such that a greater e generates a better wage distribution (in the sense of first-order stochastic dominance). That is, $W(w_f; e)$ would be a continuous cumulative distribution function with support $[0, w_m)$ where $W(w_f; e_2) \leq W(w_f; e_1)\ \forall w_f$ if $e_2 > e_1$.

Women differ in their costs of investing in education, $C(e)$. Each woman chooses e to maximize her expected utility:

$$\max_{e \geq 0} W(2\beta; e)V_U(\lambda_M) + (1 - W(2\beta; e))V_E(\lambda_M) - C(e)$$

where $V_U(\lambda_M)$ and $V_E(\lambda_M)$ are defined analogously to equation (7). Once a woman chooses her optimal e^*, she draws her wage from $W(w_f; e^*)$. If her wage is higher than 2β, she works in equilibrium. If her wage is lower, she becomes a full-time housewife.

The difference with the setup of my model is that by choosing e, each woman can directly affect the wage distribution from which she draws from. However, since the support of $W(w_f; e)$ is $[0, w_m)$, there is a probability that even an educated woman draws a wage lower than 2β. Thus, women would be distinguished by their revealed wages instead of their education investment per se. Consequently, equation (9) would also be redefined, such that λ_E equals the fraction of women who draw wages above 2β. Marriage and household time allocation decisions are unaffected since they are functions of w_f, and not e.

This alternative setup would require one to define how e translates into different wage distributions and how that also interacts with the wage distribution exogenously changing over time.

B.2 Proofs of Propositions

Proposition 1. *When α_0 and α_1 satisfy equation (5), $\underline{w}_E < \widetilde{w}_E < w_m$. When they are larger, $\widetilde{w}_E < \underline{w}_E < w_m$. When they are smaller, $\underline{w}_E < w_m < \widetilde{w}_E$.*

Proof. $\underline{w}_E < \widetilde{w}_E$ holds if $\nu_f < V_{ET}$ at $w_f = \underline{w}_E$. $\underline{w}_E$ can be found from equating V_{UT} with V_{ET}. Plug in the expression for $\underline{w}_E$ to equations (3) and (4). The inequality with regards to α is: $\alpha_0 + \alpha_1 < \frac{1}{2}(w_m - \underline{w}_E) + \beta log2$

$\widetilde{w}_E < w_m$ holds if $\nu_f > V_{ET}$ at $w_f = w_m$. Plug in w_m to equations (3) and (4). The inequality with regards to α is: $\alpha_0 + \alpha_1 > \beta log2$.

When both inequalities above are satisfied, $\underline{w}_E < \widetilde{w}_E < w_m$. □

Proposition 2. *$\widehat{e}(\lambda_M)$ is an increasing function of λ_M, and $\widehat{e}(\lambda_M) \geq 0$ always holds.*

Proof. Since $\widehat{e}(\lambda_M)$ is defined as in equation (8) and $V_U{}'(\lambda_M) = \alpha_0$, we just need to show that $V_E{}'(\lambda_M) > \alpha_0$ holds.

$$V_E{}'(\lambda_M) = \int_{2\beta}^{\underline{w}_E} (V_{EM} - V_{ET})dW + \int_{\underline{w}_E}^{\widetilde{w}_E} \alpha_0 dW + \int_{\widetilde{w}_E}^{w_m} (V_{EM} - \nu_f)dW$$

Plugging in the equations for V_{EM}, V_{ET}, and ν_f from equations (3) and (4), the expression becomes:

$$V_E{}'(\lambda_M) = \alpha_0 + \int_{2\beta}^{\underline{w}_E} (\frac{1}{2}w_E - \beta + \beta log(\frac{2\beta}{w_E}))dW + \int_{\widetilde{w}_E}^{w_m} (\frac{1}{2}(w_m - w_E) + \beta log2 - \alpha_0)dW$$

The first integral is non-negative when $w_E \geq 2\beta$. (It equals zero if w_E are all higher than $\underline{w}_E$.) By assumption (5) and that $\alpha_0 \leq \beta log2$, the second integral is positive. (It would equal zero if and only if $\alpha_0 = \beta log2$ and there is a discrete jump at $w_E = w_m$ such that $prob(\widetilde{w}_E \leq w_E < w_m) = 0$. Since $W(w_E)$ is a continuous cumulative function over $(2\beta, w_m)$, the latter condition cannot hold.) Hence ${V_E}'(\lambda_M) > \alpha_0$ and therefore ${V_E}'(\lambda_M) - {V_U}'(\lambda_M) > 0$.

Since $\widehat{e}(\lambda_M)$ is an increasing function of λ_M, it is sufficient to show that $\widehat{e}(0) > 0$. $\widehat{e}(0) = \int_{2\beta}^{\widetilde{w}_E} V_{ET} dW + \int_{\widetilde{w}_E}^{w_m} \nu_f dW - V_{UT}$. We know that $V_{ET} = V_{UT}$ when $2\beta < w_E \leq \underline{w}_E$, $V_{ET} > V_{UT}$ when $\underline{w}_E < w_E \leq \widetilde{w}_E$, and $\nu_f > V_{ET}$ when $w_E > \widetilde{w}_E$. Thus $\widehat{e}(0) \geq 0$ always holds. □

Proposition 3. *Given $W_{t-1}(.)$ and λ_{Mt-1}, if the distribution $W_{t1}(.)$ first-order stochastically dominates $W_{t2}(.)$, $F_{Et1} \geq F_{Et2}$.*

Proof. Given $W_{t-1}(.)$ and λ_{Mt-1}, λ_{Mt} is determined regardless of $W_t(.)$ (see equation (1)). $\widehat{e}(\lambda_{Mt}) = V_E(\lambda_{Mt}) - V_U(\lambda_{Mt})$. $V_U(\lambda_{Mt})$ is invariant to changes in w_E. So we just need to show that

$$V_E(\lambda_{Mt}) = \int_{2\beta}^{\widetilde{w}_E} (\lambda_{Mt} V_{EM} + (1 - \lambda_{Mt}) V_{ET}) dW_t + \int_{\widetilde{w}_E}^{w_m} (\lambda_{Mt} V_{EM} + (1 - \lambda_{Mt}) \nu_f) dW_t$$

is larger under $W_{t1}(.)$ than under $W_{t2}(.)$.

By definition of first-order stochastic dominance, $W_{t1}(\widetilde{w}_E) \leq W_{t2}(\widetilde{w}_E)$ and hence the probability weight on the second integral is relatively larger under $W_{t1}(.)$ than under $W_{t2}(.)$. Since V_{EM} is an increasing function of w_E and $V_{ET} < \nu_f$ when $w_E > \widetilde{w}_E$ (by definition of $\widetilde{w}_E$), $(\lambda_M V_{EM} + (1 - \lambda_M)\nu_f)$ is larger than $(\lambda_M V_{EM} + (1 - \lambda_M) V_{ET})$. Hence the probability weight on the larger term is larger under $W_{t1}(.)$ than under $W_{t2}(.)$.

The comparative statics follows directly from equations (9) and (10). □

Proposition 4. *Given $W_{t-1}(.)$ and λ_{Mt-1}, educated women's marriage probability is an increasing function of $W_t(\widetilde{w}_E)$. Hence if the distribution $W_{t1}(.)$ first-order stochastically dominates $W_{t2}(.)$, $p_{Et1} \leq p_{Et2}$.*

Proof. We need to show that $p_E(\lambda_{Mt})$ (as defined in equation (6)) is smaller under $W_{t1}(.)$ than under $W_{t2}(.)$. Given $W_{t-1}(.)$ and λ_{Mt-1}, λ_{Mt} does not change with regards to $W_t(.)$ (see equation (1)). $p_E(\lambda_{Mt})$ can be rewritten as $W_t(\widetilde{w}_E)(1 - \lambda_{Mt}) + \lambda_{Mt}$. Since $\lambda_{Mt} < 1$, p_{Et} is an increasing function of $W_t(\widetilde{w}_E)$. □

Proposition 5. *Suppose $W_t(.)$ first-order stochastically dominates $W_{t-1}(.)$ at all t. The decrease in p_E from $t-1$ to t is larger when (i) the drop in $W(\widetilde{w}_E)$ from $t-1$ to t is larger and (ii) the shift in $W(.)$ from $t-2$ to $t-1$ is smaller.*

Proof. Condition (i): From Proposition 4, we know that $p_E(\lambda_{Mt})$ decreases in $W_t(\widetilde{w}_E)$ given λ_{Mt}. Hence a drop in $W(\widetilde{w}_E)$ from $t-1$ to t helps decrease educated women's marriage probability.

Condition (ii): By Proposition 3 and equation (1), we know that the increase in λ_M from $t-1$ to t is larger when the (first-order stochastically dominating) change in $W(.)$ from $t-2$ to $t-1$ is larger. Hence if there is a large positive shift in the wage distribution from $t-2$ to $t-1$, λ_{Mt} would be much larger than λ_{Mt-1}. This helps increase educated women's marriage probability since $p_E(\lambda_{Mt})$ increases in λ_{Mt} (see equation (6)) given $W_t(.)$.

Both (i) and (ii) are needed for the Gold Miss phenomenon to arise. If only condition (i) holds and there was a significant wage growth from $t-2$ to $t-1$, then even if there is a large drop in $W(\widetilde{w}_E)$ at t, p_E may not fall because there is now a larger fraction of modern type in the marriage market than at $t-1$. Conversely, if only condition (ii) holds and there is only a trivial change in $W(\widetilde{w}_E)$, p_E would not fall since a woman (matched to a traditional type) does not forgo marriage unless her wage is higher than $\widetilde{w}_E$. □

Notes. Effect of mother's LFP and education on gender attitudes, among men in Japan. Data are from the 2000–2008 JGSS. See Appendix A.3 for details. Each column refers to the following statements, respectively: (1) "If a husband has sufficient income, it is better for his wife not to have a job," (2) "Men should cook and look after themselves," (3) "A husband's job is to earn money; a wife's job is to look after the home and family," (4) "A preschool child is likely to suffer if his/her mother works," and (5) "It is more important for a wife to help her husband's career than to have one herself." The dependent variable equals 1 if the respondent either "Disagree" or "Somewhat disagree" to the statements (except for (2), where the dependent variable equals 1 if "Agree" or "Somewhat agree"). Mother's LFP at age 15 equals 1 if mother had a paying job when respondent was about 15 years old. ln(Income) is the log of total personal income (in 1999 yen). Region is a set of six dummies, and urban is a set of three dummies for the size of municipality. Birth cohort is grouped into six decennial periods, from 1920–1929 to 1970–1983. I exclude respondents under age 25 or enrolled in school at the time of the survey. Robust standard errors in brackets. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

Notes. Effect of husband's country of origin and U.S. nativity on housework time, among married women from low female labor force participation (FLFP) countries. Data are from the 2003–2011 ATUS. See Appendix A.4 for details. Country of origin is defined as low FLFP if labor force participation rates of women in age group 25–34 were lower than that of the U.S. in 1985. ln(Family income) is the log of family income (in 1999 dollars). Controls for both respondent's and spouse's age and whether college graduate are included. I exclude respondents under age 25 or enrolled in school at the time of the survey. Standard errors are clustered by husband's father's birthplace. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

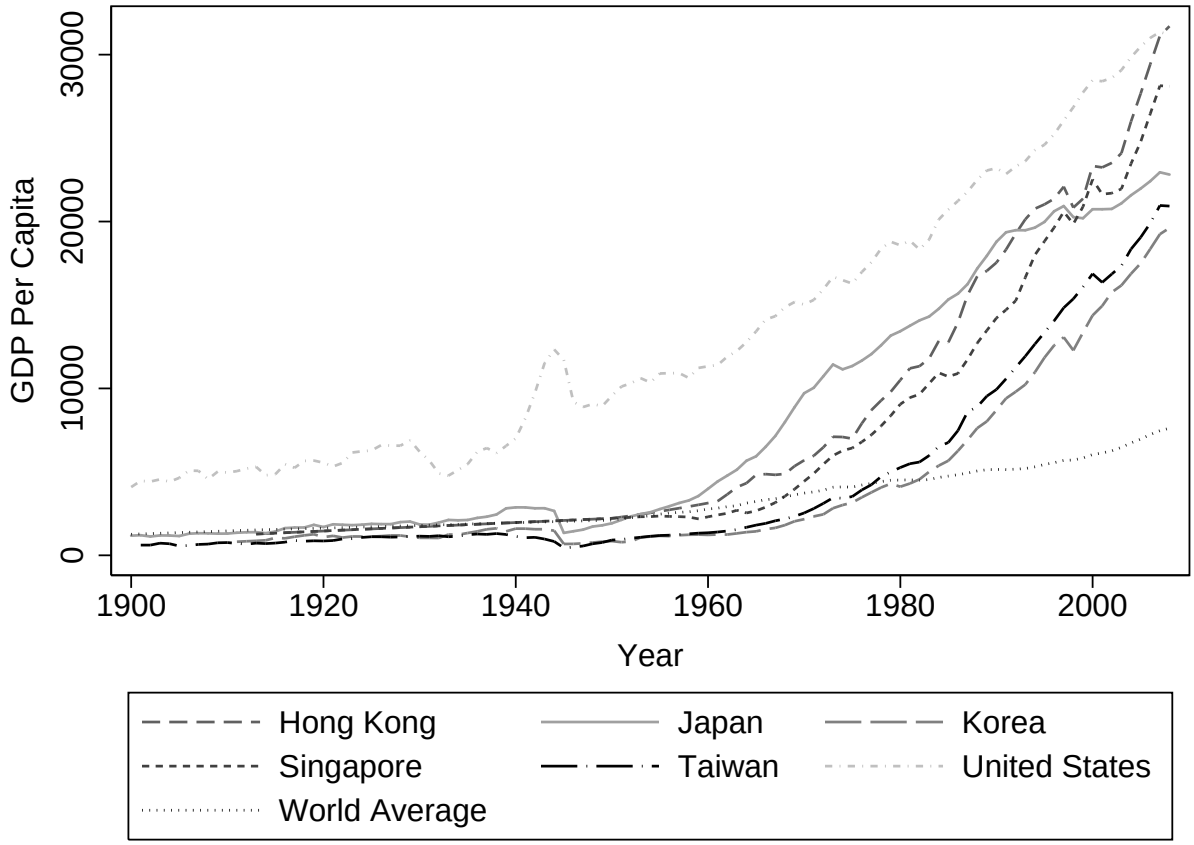
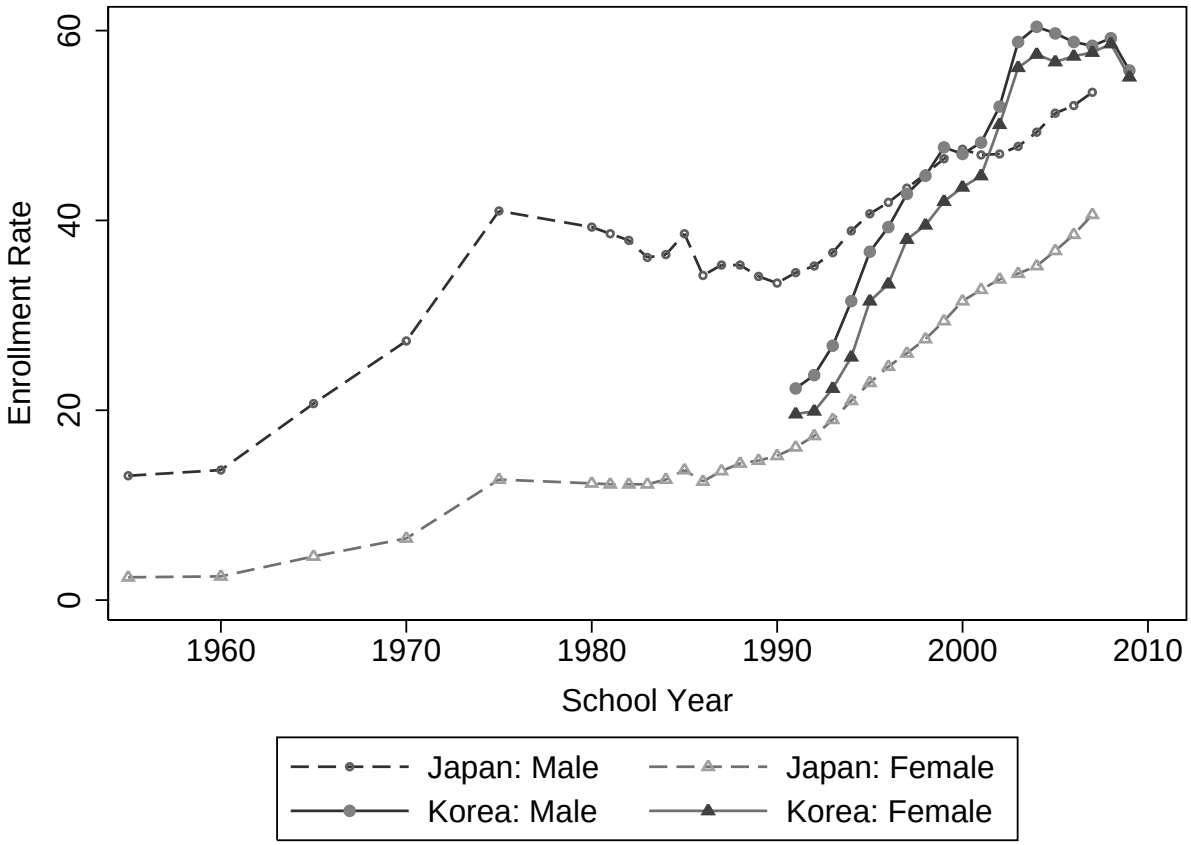
Notes. Husband's relative educational attainment, among married Korean and Japanese (KrJp) women in the U.S. Data are from the 1980, 1990, 2000 Census and 2001–2010 ACS. Educational attainment is divided into four groups: high school graduate or less, some college, four-year college graduate, and graduate and professional degrees. The dependent variable equals 1 if husband's education is higher than wife's by at least one step. Birth cohort is grouped into six decennial periods, from 1925–1934 to 1975–1985. I exclude respondents who have migrated to the U.S. under age 3 or over 17, who are under age 25, or still attending school at the time of the survey. Robust standard errors in brackets. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

Figure 1: GDP Per Capita Trends of Developed Asian Countries



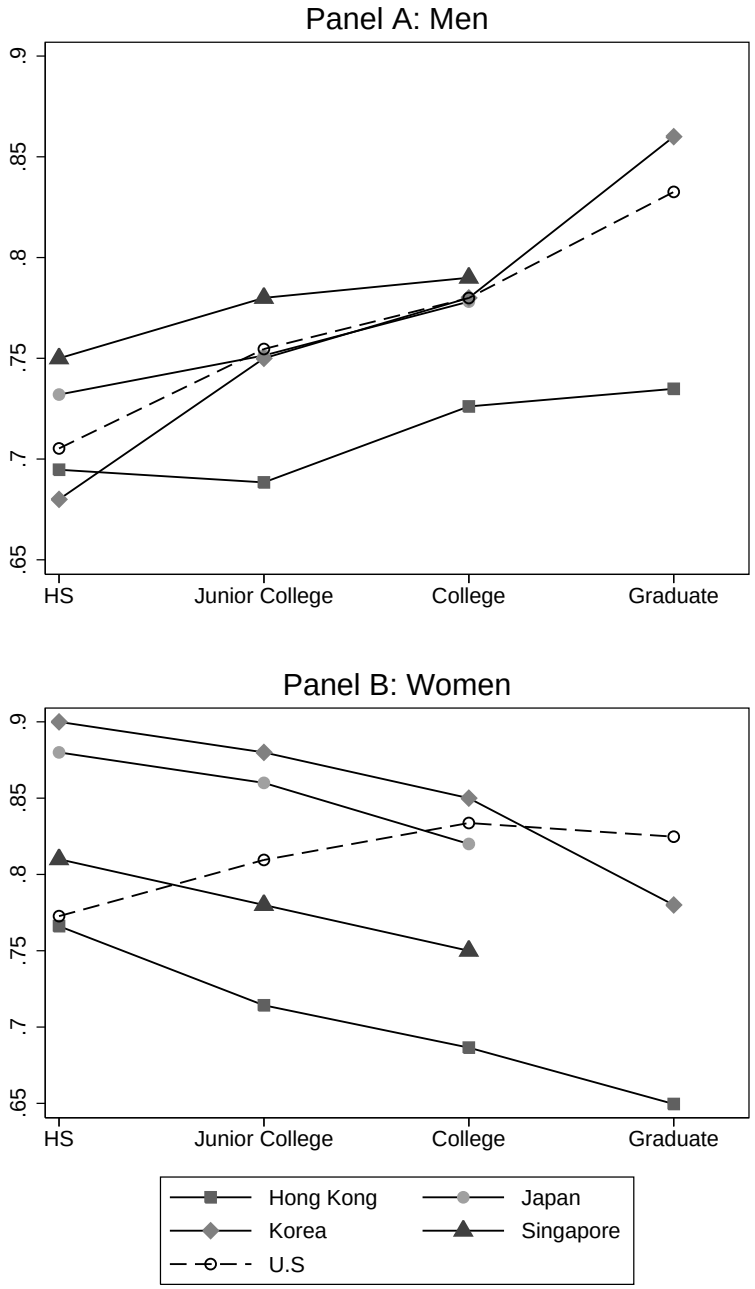
Notes. GDP per capita measured in 1990 international (Geary-Khamis) dollar units. Data are taken from Angus Maddison's Historical Statistics of the World Economy.

Figure 2: College Enrollment Rates in Japan and Korea



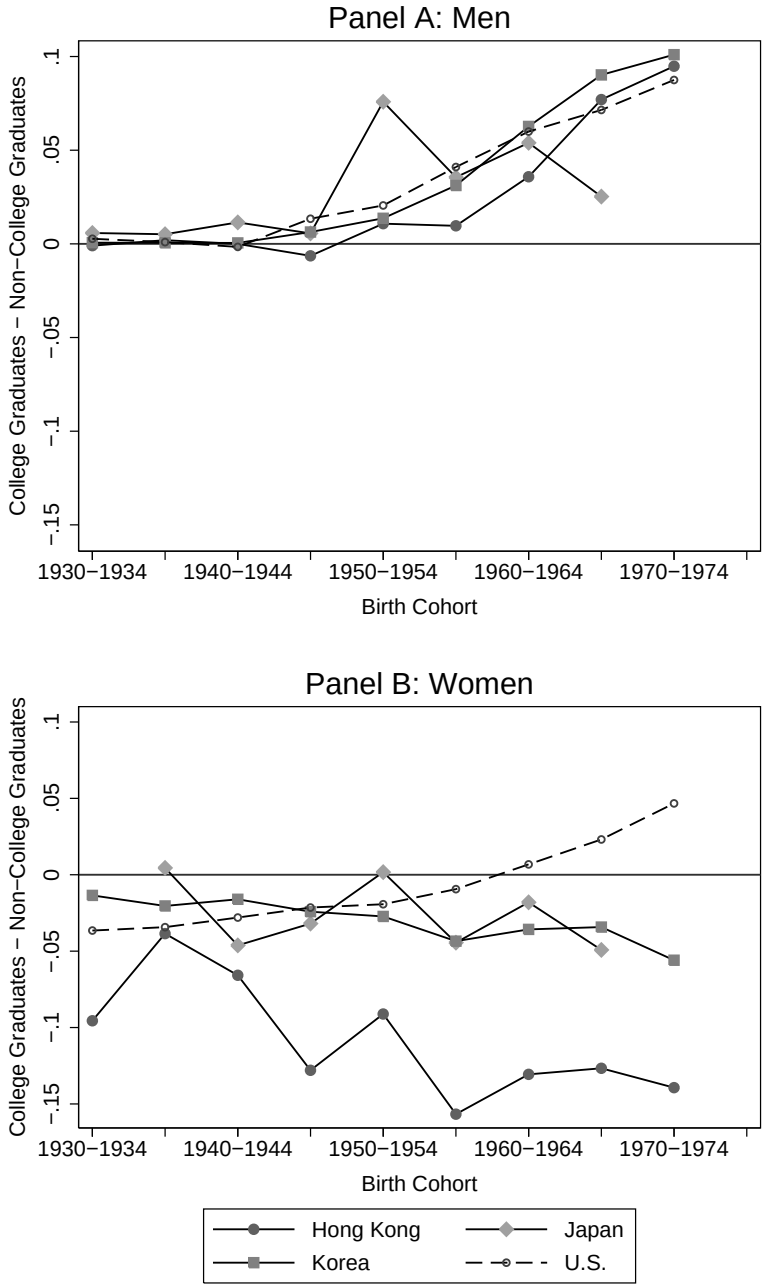
Notes. College enrollment rates in Japan and Korea by sex. Data are from the Basic School Survey collected by the Japanese Ministry of Education, Culture, Sports, Science and Technology, and the Statistical Yearbook of Education collected by the Korean Educational Development Institute and the Korean Ministry of Education, Science, and Technology. Enrollment rate is measured as the number of entrants to colleges divided by the number of graduates from middle school three years before (Japan), or divided by the number of graduates from high school that year (Korea). Primary and secondary education (until 9th grade) is compulsory in both countries: enrollment in middle school is higher than 99 percent throughout the period. In Korea, more than 95 percent of middle school graduates go on to high school throughout this period. College does not include junior colleges.

Figure 3: Fraction Ever Married by Sex and Education, Ages 35–39



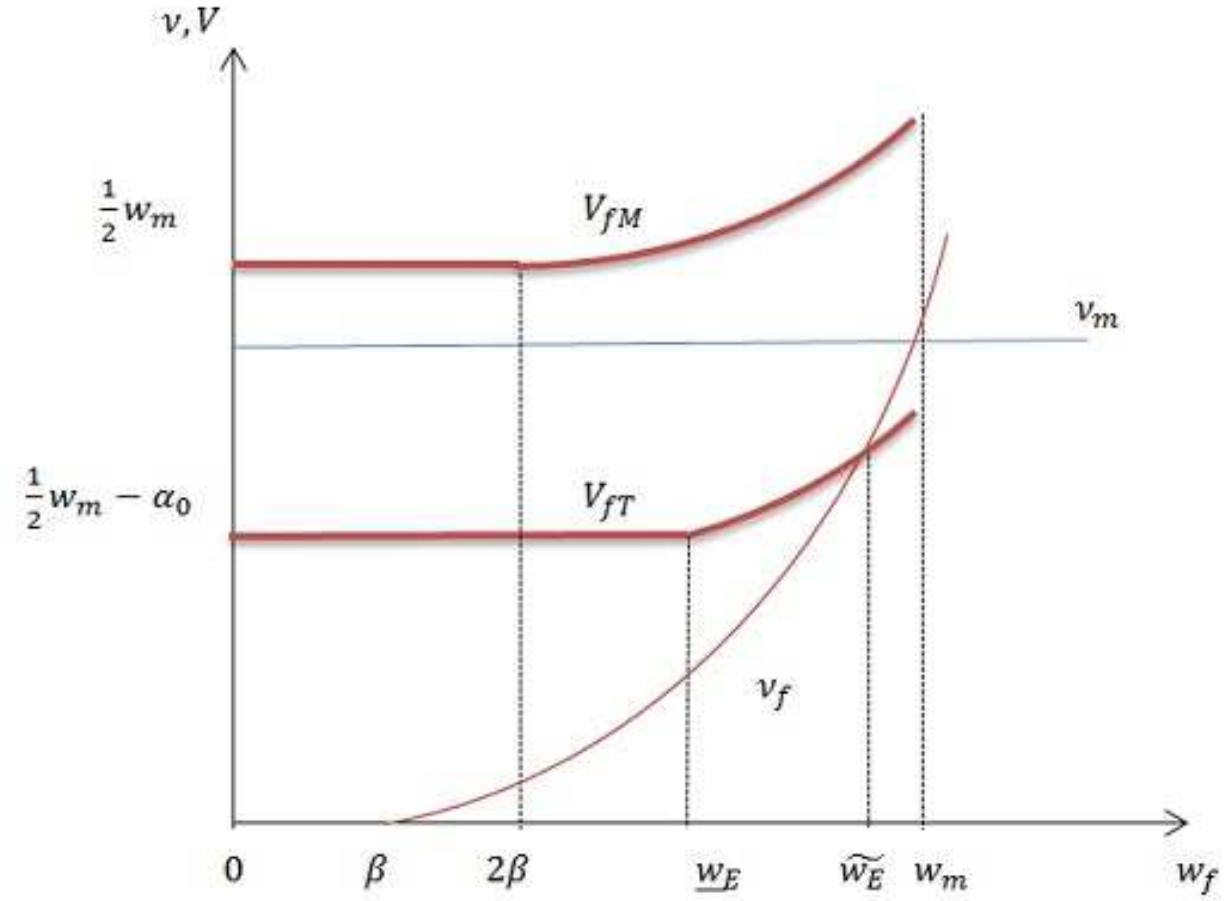
Notes. Fraction ever married among men and women in age group 35–39 by educational attainment level in each country. Data are from the 2006 Hong Kong Population Census, the 2000 Japanese Population Census, summary tables from the 2010 Korean Population Census, Singapore's "Population in Brief 2011," and the 2010 American Community Survey. Each country has a different education system but I divide them into four common groups for comparison. High school refers to "Senior Secondary" schools in Hong Kong, high schools in Japan, Korea, and the U.S., and "Post-Secondary" schools in Singapore. Junior college refers to "Post-secondary (non-degree)" in Hong Kong, "Junior College/Vocational School" in Japan, less than four-year colleges in Korea and the U.S., and "Diploma & Professional Qualification" in Singapore. College refers to "Post-secondary (degree)" in Hong Kong and four-year universities in other countries. See Appendix A.2 for details. Since Japan and Singapore do not report separately for graduate school, "College" also includes those with more than a college degree in these countries.

Figure 4: Difference in Fraction Ever Married Between College Graduates and Non-College Graduates, Over Age 35



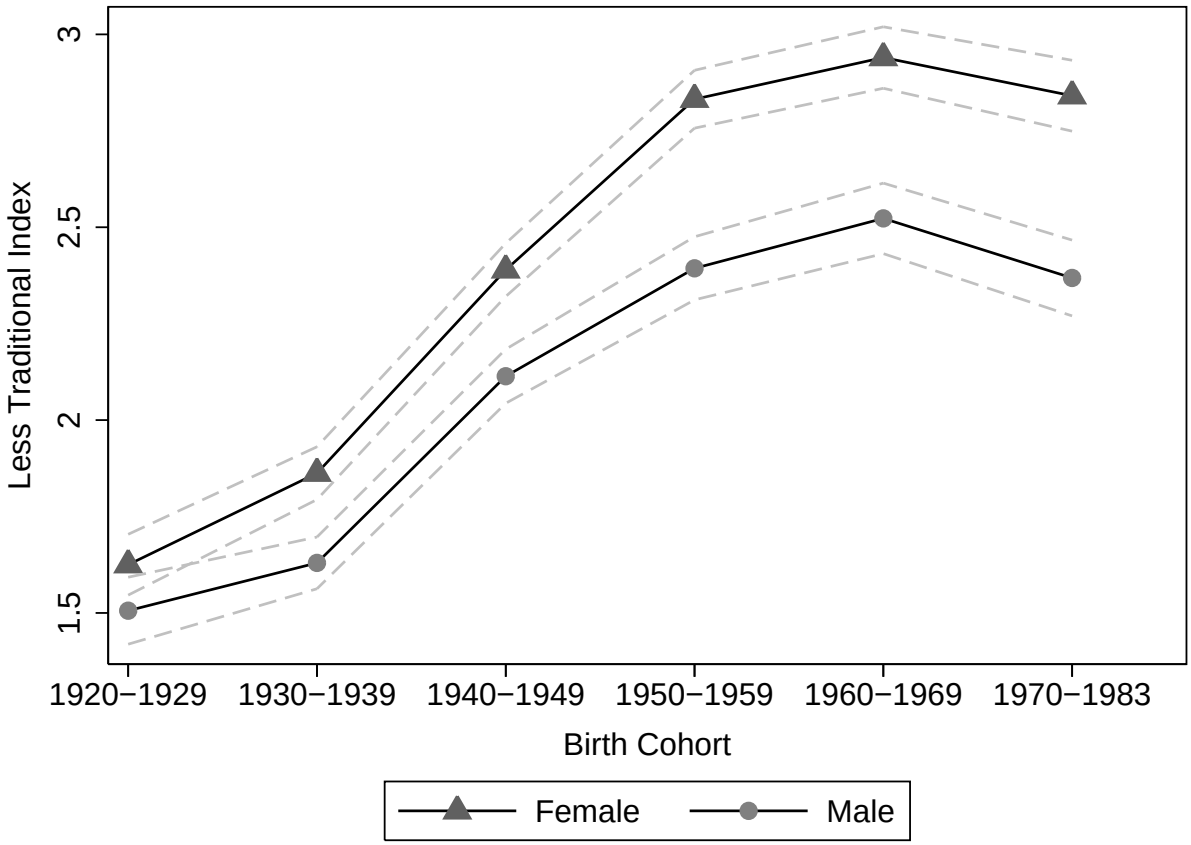
Notes. Difference in the fraction ever married between college graduates and non-college graduates, among men and women over age 35 in each birth cohort. Data are from the 2006 Hong Kong Population Census, 2000–2008 Japanese General Social Survey, 1995 and 2000 Korean Population Census, 2012 Korean Economically Active Population Survey, and the 2010 American Community Survey. See Appendix A for details. The 1965 cohort in Japan includes birth years 1965–1972 and the 1970 birth cohort in Korea includes birth years 1970–1976. College refers to four-year colleges in Japan, Korea and the U.S., and post-secondary (degree) levels in Hong Kong. I exclude respondents still attending school at the time of the survey.

Figure 5: Woman's Utility as a Function of Her Wage



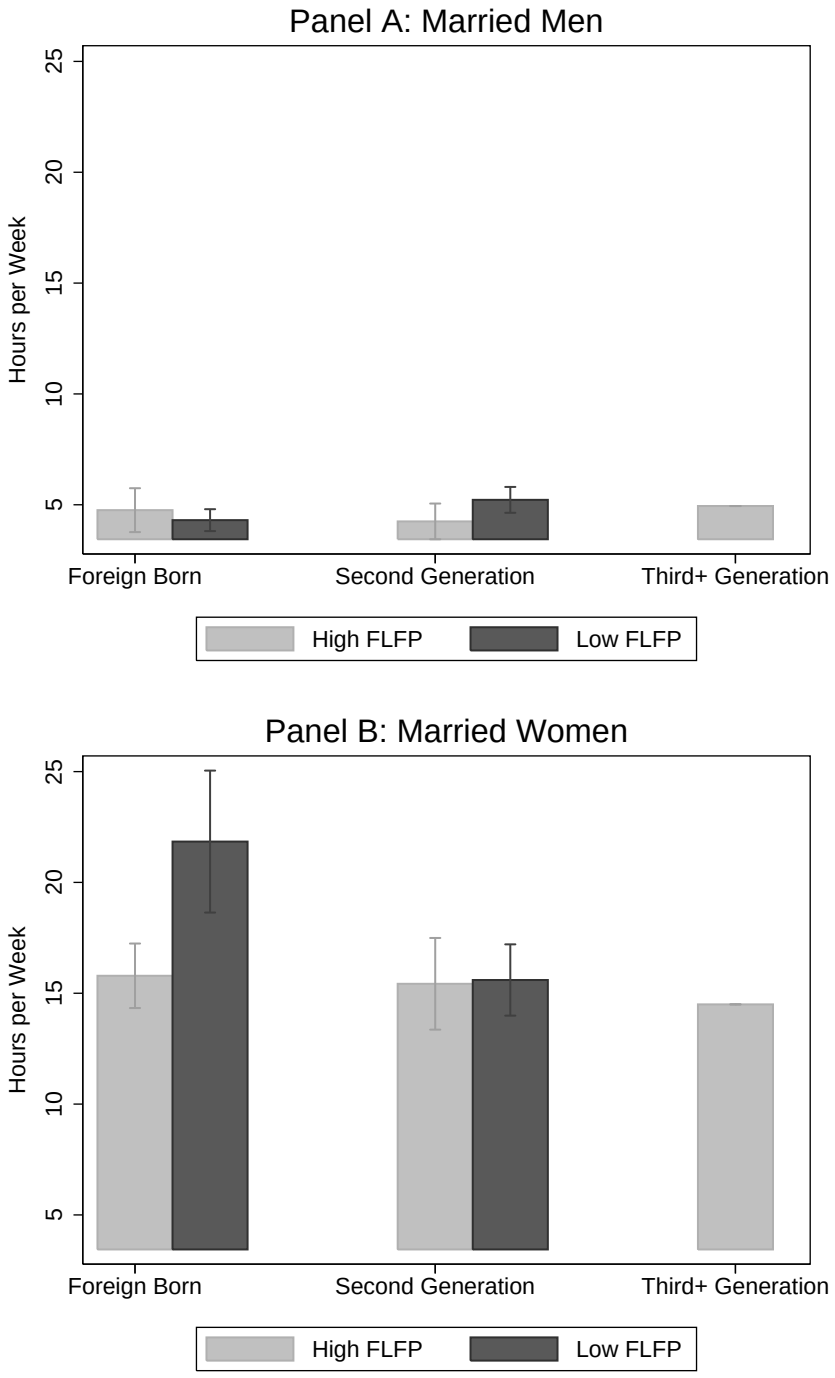
Notes. V_{fM} and V_{fT} are a woman's utility in marriage when her husband is modern and traditional type, respectively. ν_f is the utility of a single woman and ν_m is the utility of a single man. β, 2β, and $\underline{w}_E$ are the wages where a woman in each of the three cases are indifferent between staying at home and working. $\widetilde{w}_E$ is defined as the wage where ν_f crosses V_{fT}.

Figure 6: Evolution of Gender Attitudes in Japan



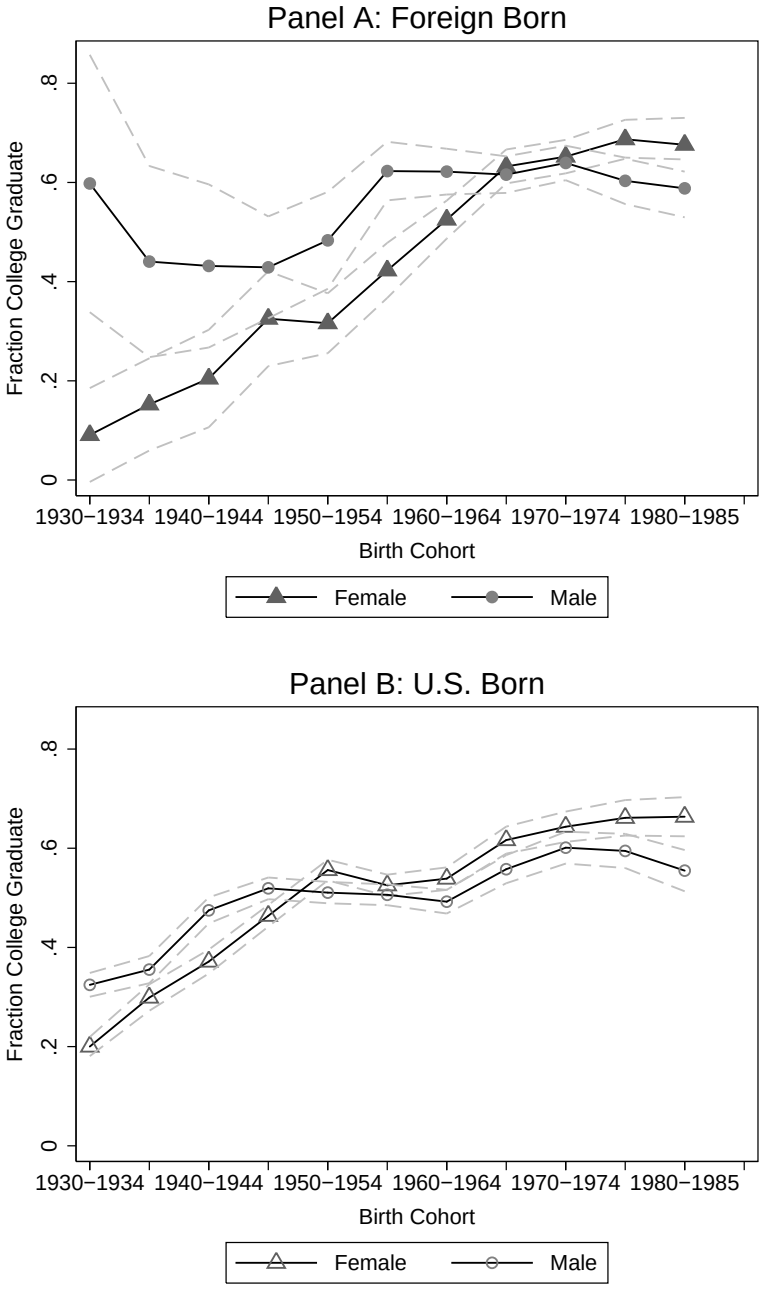
Notes. The degree of traditionality by birth cohort, among men and women in Japan. Data are from the 2000–2008 JGSS. See Appendix A.3 for details. The "less traditional index" ranges from 0 to 5 and is defined from whether the respondent agrees or disagrees to the following statements: "If a husband has sufficient income, it is better for his wife not to have a job," "Men should cook and look after themselves," "A husband's job is to earn money; a wife's job is to look after the home and family," "A preschool child is likely to suffer if his/her mother works," and "It is more important for a wife to help her husband's career than to have one herself." The index equals 0 if the response is traditional with regards to all five questions (i.e. disagreed to second statement and agreed to others), and 5 if less traditional with regards to all five questions. I exclude respondents under age 25 or enrolled in school at the time of the survey. Robust standard errors are used to calculate 95 percent confidence intervals.

Figure 7: Housework Time by Country of Origin and Generation



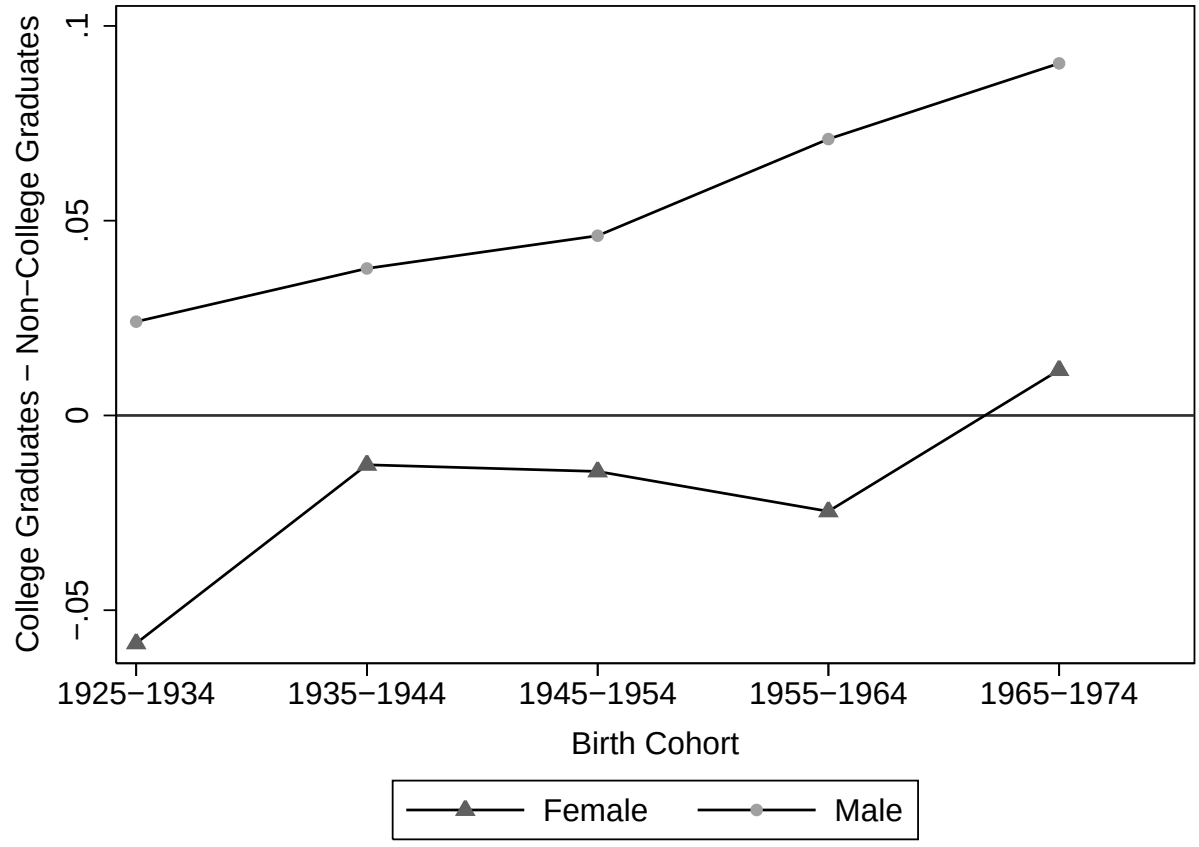
Notes. Mean estimates of time spent on housework among married men and women by country of origin and generation since migrating to the U.S. Data are from the 2003–2011 ATUS. See Appendix A.4 for details. Country of origin is defined as high (low) FLFP if labor force participation rates of women in age group 25–34 were higher (lower) than that of the U.S. in 1985. I exclude respondents under age 25 or enrolled in school at the time of the survey. Standard errors clustered by father's birthplace are used to calculate 95 percent confidence intervals.

Figure 8: Fraction College Graduate, Koreans and Japanese in the U.S.



Notes. Mean estimates of fraction college graduate by sex and birth cohort, among Koreans and Japanese in the U.S. Data are from the 1980, 1990, 2000 Census and 2001–2010 ACS. Foreign born only includes those who migrated to the U.S. between ages 3–17. I exclude respondents under age 25 or still attending school at the time of the survey. Robust standard errors are used to calculate 95 percent confidence intervals.

Figure 9: Difference in Fraction Ever Married Between College Graduates and Non-College Graduates, Koreans and Japanese Over Age 35 in the U.S.



Notes. Difference in the fraction ever married between college graduates and non-college graduates, among Koreans and Japanese in the U.S. over age 35 in each birth cohort. Data are from the 1980, 1990, 2000 Census and 2001–2010 ACS. I exclude respondents who have migrated to the U.S. under age 3 or over 17, or still attending school at the time of the survey.

Table A1: Descriptive Statistics, JGSS Sample

	Men		Women	
	Mean	SD	Mean	SD
Birthyear	1953.28	(15.79)	1951.98	(16.72)

Age at immigration	10.72	10.50		
	(4.35)	(4.54)		
N	7,189	7,366	45,238	44,794

Notes. Means and standard deviations by sex and nativity, among Koreans and Japanese in the U.S. Data are from the 1980, 1990, 2000 Census and 2001–2010 ACS. See Appendix A.5 for details. Foreign born only includes those who migrated to the U.S. between ages 3–17. LFP is an indicator variable that equals 1 if the respondent is in the labor force. ln(Income) is the log of total personal income (in 1999 dollars). "Speaks English well" is an indicator variable that equals 1 if the respondent "speaks only English," "speaks English very well," or "speaks English well" and 0 if "does not speak English" or "can speak English but not well." I exclude respondents under age 25 or still attending school at the time of the survey. All observations are weighted by the IPUMS person weight.

Table A5: Gender Gap in Spouse's Ethnicity and U.S. Nativity, Koreans and Japanese in the U.S.

	(1)	(2)	(3)	(4)

N	57,253	57,253	57,253	57,253
Dependent variable mean	0.21	0.38	0.05	0.36

Notes. Spouse's ethnicity and nativity, among married Korean and Japanese (KrJp) in the U.S. Data are from the 1980, 1990, 2000 Census and 2001–2010 ACS. Foreign born spouse refers to non-U.S. born, regardless of spouse's age at migration. The omitted group is Korean and Japanese foreign born male. Birth cohort is grouped into six decennial periods, from 1925–1934 to 1975–1985. I exclude respondents who have migrated to the U.S. under age 3 or over 17, who are under age 25, or still attending school at the time of the survey. Robust standard errors in brackets. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

Table A6: Effect of Korean and Japanese Female Composition on Wife's Ethnicity, Korean and Japanese Men in the U.S.

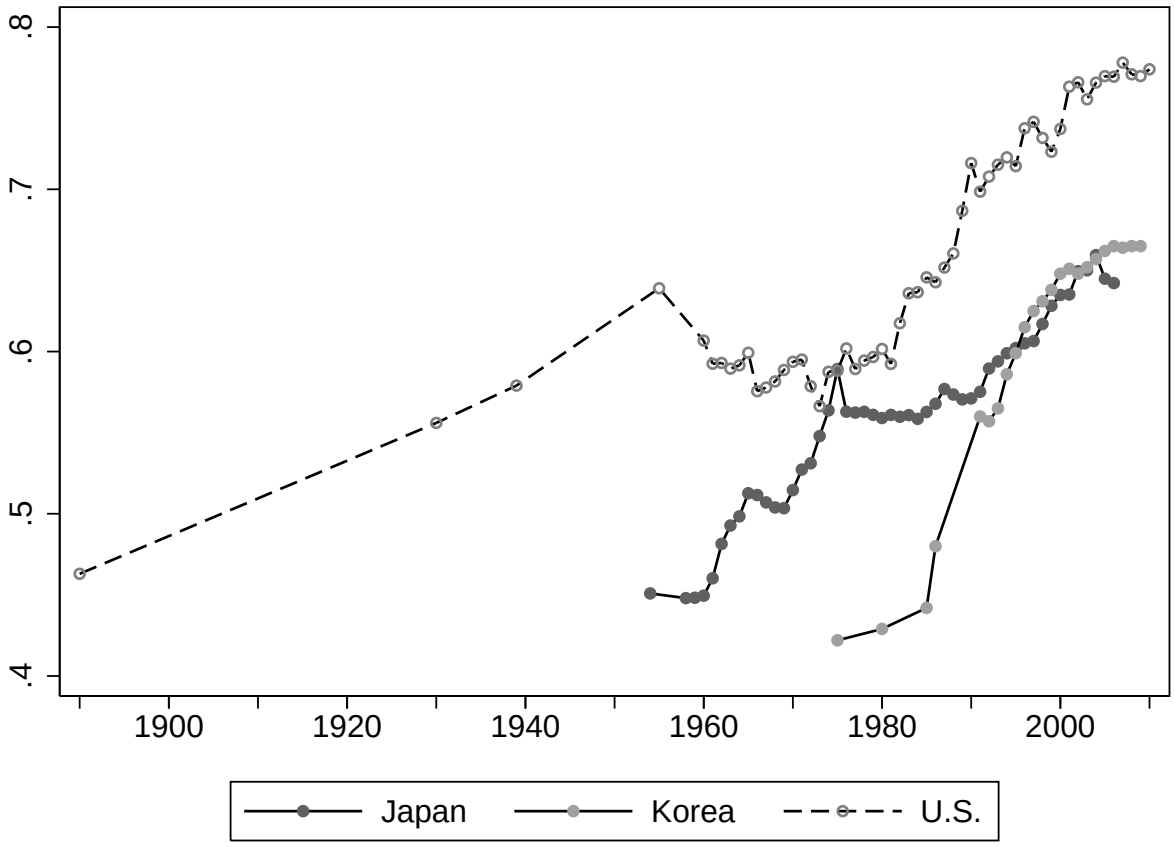
Cohort FE	Yes	Yes	Yes	Yes
N	2,721	10,635	1,458	12,132
Dependent variable mean	0.21	0.43	0.23	0.39

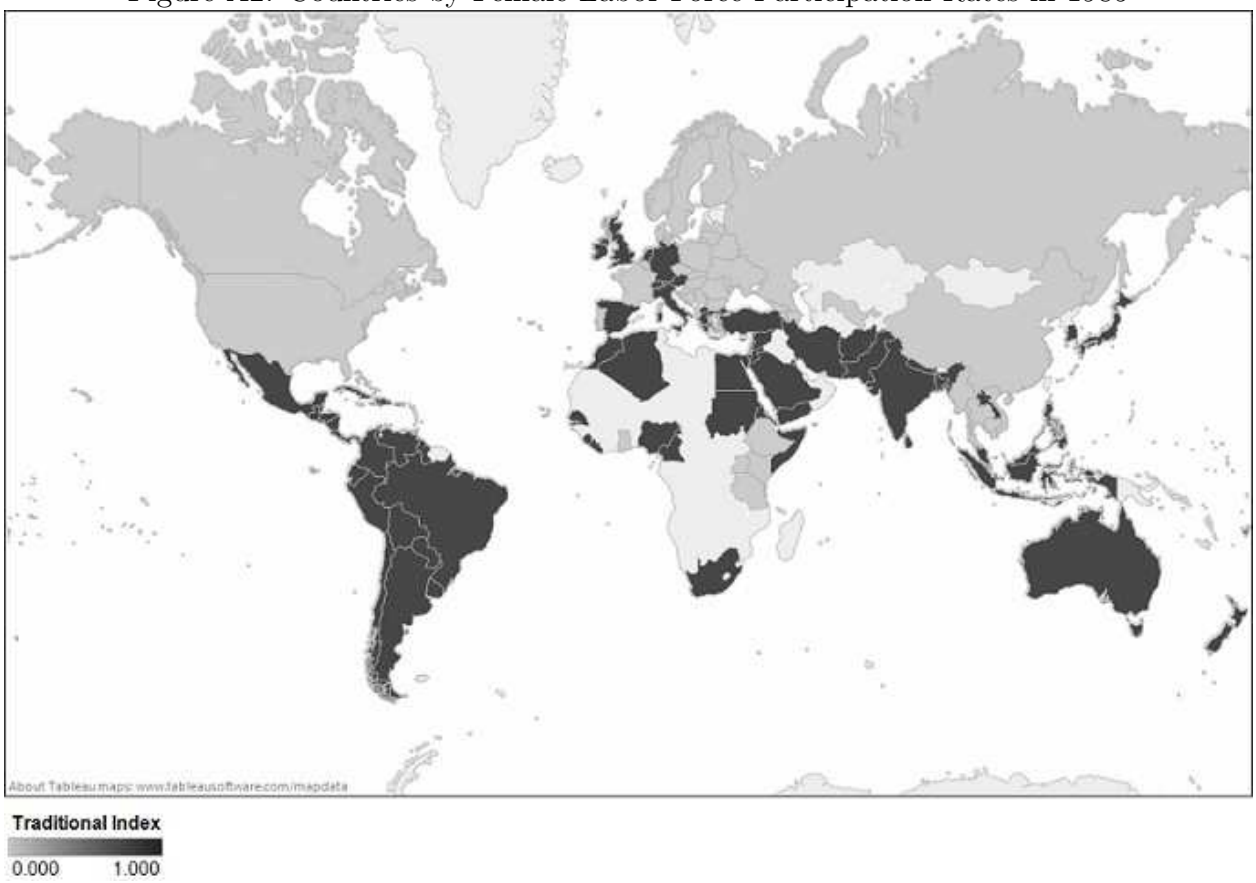
Notes. Effect of fraction foreign born among Korean and Japanese (KrJp) women in one's state and cohort on wife's ethnicity, among married Korean and Japanese men in the U.S. Data are from the 1980, 1990, 2000 Census and 2001–2010 ACS. Fraction foreign born among women (men) is the number of foreign born (regardless of age at migration) divided by the number of Korean and Japanese women (men) by state and cohort. State-cohort cells with no Korean or Japanese women (men) are excluded. ln(Total number of KrJp) is the log of the total number of Korean and Japanese women (men) by state and cohort. Birth cohort is grouped into six decennial periods, from 1925–1934 to 1975–1985. I exclude respondents who have migrated to the U.S. under age 3 or over 17, who are under age 25, or still attending school at the time of the survey. Standard errors are clustered by state and cohort. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

Figure A1: Female-to-Male Earnings Ratios for Full-Time, Year-Round Workers



Notes. Female-to-male earnings ratios in Japan, Korea and the U.S.
Japanese data are from the Statistics and Information Department of the Ministry of Health, Labour, and Welfare, and measures female-to-male average monthly cash earnings of regular employees. Data excludes workers in small enterprises (fewer than 10 employees). Part-time workers are included until 1969. Years 1961, 1964, 1967, and 1970 exclude workers in service industries.
Korean data are from the 1975–2009 Occupational Wage Survey, and measures female-to-male median earnings of full-time, year-round workers. Data excludes workers in small enterprises (fewer than 10 employees until 1998 and fewer than 5 since 1999), self-employed, family workers, temporary workers, and public sector workers. All industries are covered until 1986. Agriculture, forestry, hunting, and fishing are excluded thereafter. Earnings include only wage or salary income.
U.S. data for 1890 and 1930 are from Goldin (1990) Table 3.2, and are based on weighted averages across occupations of annual, full-time earnings for men and women. Ratios for 1939 are from the 1940 U.S. Census of Population; 1955 is from the U.S. Department of Commerce, Bureau of Census, Current Population Reports, Series P–60; 1960 and on are from U.S. Census Bureau, Current Population Survey, Annual Social and Economic Supplements, Table P–38. Earnings include only wage or salary income before 1966 and total earnings subsequently. Data refer to civilians 14 years and over through 1978 and 15 years and over beginning 1979.

Figure A2: Countries by Female Labor Force Participation Rates in 1985



Notes. High and low female labor force participation (FLFP) countries. FLFP data are from the United Nations (UN) and are matched to father's birthplace in the ATUS sample. See Appendix A.4 for details. Father's birthplace is defined as high (low) FLFP if labor force participation rates of women in age group 25–34 were higher (lower) than that of the U.S. in 1985. Total of 121 countries in the UN data are matched to the ATUS sample—42 high FLFP (light gray) and 79 low FLFP (dark gray). Unmatched countries (either because they do not have data on FLFP or because they are not available as father's birthplace in the ATUS) are in white.
