Effect of sleeping position on nasal patency in newborns
O Olarinde, A R Banerjee, C O’Callaghan

Sleeping posture has been implicated in the pathophysiology of sudden infant death syndrome (SIDS). The nasoaxillary reflex is the decreased ipsilateral nasal airway and increased contralateral airway in response to lying on one side. The aim of this study was to test the hypothesis that there is a nasoaxillary reflex in neonates. We investigated the effect of supine and lateral sleeping positions on nasal patency using acoustic rhinometry in 11 healthy newborns. The implications of our findings in SIDS are discussed.

SUBJECTS AND METHODS
Eleven healthy term newborn infants were examined at 1–4 days of age. Babies with nasal symptoms, nasal or facial deformities, and those on medication were excluded.

Acoustic rhinometry was carried out with a RHIN 2000 miniprobe (Rhinometrics A/S, Lynge, Denmark; software version 2.6), according to recommendations by Hilberg and Pederson. Local research ethics committee approval and written consent from the babies’ parents were obtained. Acoustic rhinometry measures cross sectional area/distance mapping of the nasal cavity, by emitting wide band noise into the nose, and analysing the reflected sound. The incident and reflected waves are recorded by a microphone and digitally analysed by the software, at a rate of 20 times per second. It provides a clear and objective cross sectional area at every point in the nasal cavity, both graphically and in figures. The use of wide band noise ensures unique high speed and stability. Acoustic rhinometry must be carried out in cooperative subjects, and therefore all measurements were carried out in babies in non- arousable states to ensure cooperation. Measurements were made in the following postures and after the following times: (a) when lying supine for 30 minutes; (b) after lying on one side for 15 minutes; (c) after lying supine again for 30 minutes; (d) after lying on the other side for 30 minutes. A plot of the nasal cross sectional area against distance (acoustic rhinogram) was generated using the RHIN 2000 software. A mean curve from three readings taken within one minute of each other was computed for each nasal cavity and for each of the postures. The software also computed the volume of the nasal cavity.

RESULTS
Three infants awoke during the examination, and their results were excluded. Mean gestational age was 39.8 weeks (range 38–41.6). Mean birth weight was 3200 g (range 1900–4800). Seven of the infants were female and one was male. Mean (SD) age at which the measurements were taken was 37.1 (23.8) hours.

Table 1 shows the changes in acoustic rhinometry measurements. Repeatability, expressed as the coefficient of variation, was assessed from three measurements each from the 11 infants studied. The repeatability was 4.4%, 9.1%, 5.2%, and 8.3% for MCA10, MCA10-40, Vol10, and Vol10-40 respectively.

DISCUSSION
We were unable to show a nasoaxillary reflex in healthy newborn infants. Indeed we found a significant decrease in the total minimum cross sectional area of the nasal cavity when newborns were turned from a supine to a lateral position, associated with a decrease in the total nasal volume.

In 1996, the American Academy of Paediatrics recommended non-prone—that is, supine and lateral—sleeping positions in an attempt to reduce the incidence of sudden infant death. In 1992 the American Academy of Paediatrics recommended non-prone—that is, supine and lateral—sleeping positions in an attempt to reduce the incidence of sudden infant death. In 1996, this advice was modified to recommend that infants should sleep in the supine position only. This was due to reports from England that the risk of SIDS was slightly greater for infants placed on their sides compared with those placed supine. This advice has been associated with an appreciable decrease in the incidence of SIDS. In the latest policy statement published by the American Academy of Paediatrics, the supine position has unequivocally been recommended as being preferred to any other position to prevent SIDS.

Suggestions as to why the supine position confers protection against SIDS include simple suffocation by rebreathing, increased nasal bacterial load, increased respiratory work of breathing, and increased upper airway secretions associated with the prone position. Our study is the first to investigate the effect of sleeping posture on nasal patency and nasal volume. The nasoaxillary reflex as described in adults is congestion of the dependent nasal cavity and decongestion of the other cavity when lying on one side. This reflex has not been described in any paediatric age group. It is a protective reflex that ensures the uppermost nasal airway (when lying on one side) is patent when lying on that side. The fact that the nasoaxillary reflex could not be demonstrated opens the question as to when it actually develops between the newborn period and adulthood. Our results may be affected by the spontaneous change in nasal resistance over time in each nasal cavity—that is, the nasal cycle—although this has not been observed in neonates. The finding that the total minimal cross sectional area decreases when infants move from a supine to a lateral sleeping position is of interest. As newborns tend to be obligate nose breathers, a decrease in the minimal cross sectional area of the nasal cavity is likely to be linked to an increase in nasal resistance and in the work of breathing. Our study was performed in healthy newborns, and it is unclear whether similar results would be found in children later in infancy or in those suffering from an upper respiratory tract infection.

The effect of supine and prone sleeping position on nasal patency in infants within the age group most prone to SIDS—
