To my parents

ACKNOWLEDGEMENTS

Throughout my graduate studies, it has been an honor and an intellectual challenge to have Eliot Moss as my advisor. The imprint of his scientific method on my development is deep, and I trust that it is reflected in the present work.

I have been fortunate to have Kathryn McKinley as my unofficial second advisor. I am grateful to her, not only for her incisive technical commentary, but also for her unflagging enthusiasm and encouragement.

I owe a debt of gratitude to Steve Heller and his group at Sun Microsystems Laboratories for allowing me to use an experimental Java virtual machine, and especially to David Detlefs, who tirelessly explained to me the intricacies of garbage collection in that system, and ran many weeks of trace generation.

This project could not have been realized without the past efforts of members of the Object Systems Laboratory: Tony Hosking, Amer Diwan, Rick Hudson, and Eric Brown, who designed and implemented the garbage collector toolkit and the Smalltalk system I have used. I should also like to acknowledge the support of the current group members: John Cavazos, Asjad Khan, Todd Wright, Abhishek Chandra, and Sharad Singhai; their hard system-building work provided the impetus to carry on with this study. John Ridgway has always found the time to guide me through the hidden corners of typesetting, and I thank him for that. It has been a great pleasure to work with them, and with many other members of the laboratory over the years.

I should like to acknowledge the benefit of discussions I have had during the development of the present work with Cathy McGeoch, Andrew Appel, and Amer Diwan. The dissertation itself has been greatly improved by the comments of my examining committee members Jack Wileden and Mani Krishna.

Upon my arrival in the town of Amherst I had the good fortune to come to know Mrs Joann C. Scott, and I am grateful for the friendship and wisdom she has shown me ever since.

Lastly, I am grateful to my parents and my sister for their persistent encouragement and unquestioning confidence. I thank my parents for their support throughout the years of my studies, which made this work possible, and for having instilled in me the spirit of free inquiry, which made it worthwhile.

——

This work has been supported by the National Science Foundation under grant IRI-9632284, and by gifts from Digital Equipment Corporation (now Compaq), Sun Microsystems, and Hewlett-Packard.

ABSTRACT

PROPERTIES OF AGE-BASED AUTOMATIC MEMORY RECLAMATION ALGORITHMS

FEBRUARY 1999

Directed by: Professor J. Eliot B. Moss

Dynamic memory management enables a programmer to allocate objects for arbitrary preiods of time. It is an important feature of modern programming languages, and is fundamental to object-oriented languages. Automatic reclamation, also known as garbage collection, automates the detection of the time when a data item can no longer be used.

The work described herein considers garbage collection algorithms that base their decisions solely upon the relative age of data. This age-based class of algorithms generalizes previously defined generational garbage collection algorithms and includes promising new algorithms. The work identifies relevant performance factors and reports them for a set of object-oriented benchmark programs, establishing a fair comparison by imposing uniform maximum space constraints. A precise tracing and garbage collection algorithm evaluation framework provides accurate results and thus meaningful comparisons.

The results indicate, contrary to assumptions in the literature, that the new algorithms copy less data than the generational algorithms, even though they retain a higher percentage of reclaimable data. In agreement with the assumptions in the literature, the results indicate that generational algorithms do less pointer-tracking work. Thus, given suitable relative costs of copying and pointer-tracking, the new algorithms perform better. Estimations of the relative costs for a typical modern processor suggest that the new algorithms are usually superior.

CHAPTER 1

INTRODUCTION

Garbage collection, the automatic reclamation of dynamically allocated memory, is a mature memory-management technique. It has been in use since 1958 [McCarthy, 1960] and is now accepted as a customary element for dynamic memory management in run-time systems of modern programming languages, especially object-oriented ones, for reasons of safety and for its clear software engineering benefits [Gosling *et al.*, 1996]. The increasing acceptance of object-oriented languages makes it more important than ever for garbage collection to work as fast as possible.

Multi-generational copying collectors are the most popular memory reclamation algorithms in use today. Generational collectors have two real advantages over original non-generational collectors: pause times are shorter (on average), and total cost is lower.

There are, however, three tenets that are commonly held as explanations why generational collectors have these advantages, and that have discouraged exploration of alternative strategies. The first has to do with a property, empirically confirmed in object-based systems, that young objects die fast (more precisely, that object mortality is a decreasing function). The popular wisdom is that generational collectors exploit this property by concentrating effort on collecting young objects. Furthermore, whenever only a part of the heap is collected at once, the remainder must be assumed live for the purposes of the collection, and all pointers from outside the region collected into it are roots of the collection. This approximation is conservative, and considers more data live than is actually the case, and thus copying cost is greater. The second tenet is that this excess copying effort is small in generational collection because pointers from outside the region into it are, by construction, pointers from older objects to

younger objects, and such pointers are few. The third tenet is that for the same reason it is easy to maintain the write barrier (actions taken during the execution of the program when a pointer is stored) and remembered sets (the sets of pointers crossing into a region).

Taken together, these three tenets do more than explain the good performance of generational collection. They have been understood in the past to rule out using any strategy that might collect older objects in preference to younger. Any such strategy would apparently concentrate effort on regions of lower mortality. It would also cause the collected region to have many incoming pointers from outside, thus from younger objects, and have both a high excess copying penalty and a high maintenance cost for the write barrier and remembered sets. Our study shows that, although each of the three tenets is intuitively and plausibly based on truthful observations of particular garbage collectors' behavior, alternatives to youngest-first generational collection are nevertheless feasible. The several plausible inferences drawn from the observations do not in fact rule out good incremental copying collectors other than generational: as we shall discover, they merely set the stage for a performance trade-off.

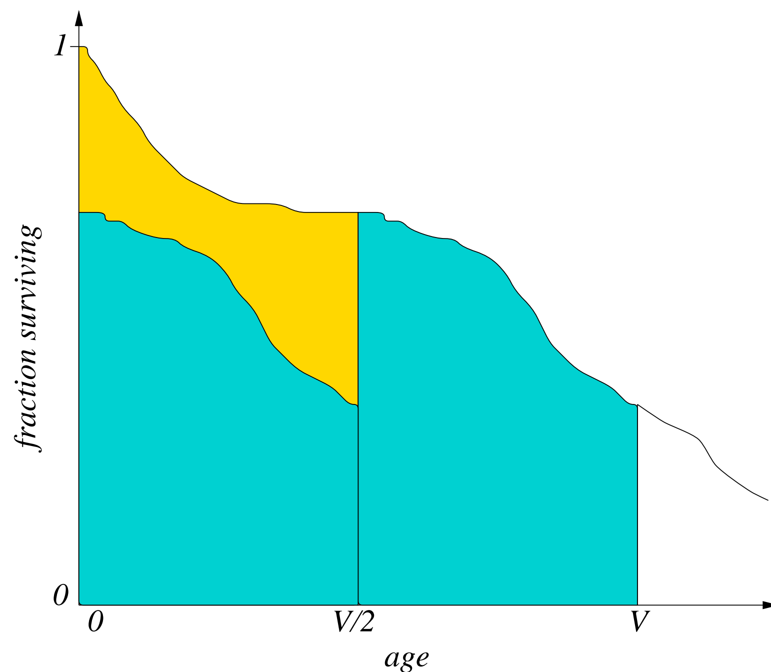

Figure 1.1. Surviving objects in a newly allocated area.

First, the intuition that effort should go to regions with high mortality is countered by the intuition that within a given area that has been newly allocated, its older half has less live data than its younger half, so it ought to be better to collect the older half.[1] A plot of the survivor function of the distribution of object lifetimes (Figure 1.1) graphically illustrates this fact—the survivor function is always a decreasing function, thus the area under the curve, which is the amount of surviving data, is smaller in the segment $[V/2, V]$ than in the segment $[0, V/2]$. In fact, it would be best to collect just the oldest object in the area. Figure 1.2 illustrates the point: imagine that newly allocated objects are placed in a queue, which plays the role of the youngest generation in generational collectors (also known as the *nursery*). When objects emerge from the queue, they are tested for liveness. Ideally, the length of the queue should be equal to the lifetime of each object, so that no object exits the queue alive. However, objects have diverse lifetimes, which a queue of fixed length cannot match. Yet if objects allocated in close succession have similar lifetimes, then the queue can manage them well, and if it can adjust the queue length to the objects' lifetimes, so much the better. Our design for the deferred older-first collector in Section 3.1.1, p.26, can be seen as an attempt to realize an approximation to a collection queue, within the restrictions of a finite and fixed space available for the queue and its survivors.

Figure 1.2. A collection queue.

With regard to the empirical observations on which the first tenet was founded, we should point out that, even though a decreasing mortality has been attested in all measured systems

[1]This point is subtle. For instance, in discussing garbage collection in the implementation of SML, Appel states both that *the longer one waits before a collection, the more records have turned into garbage* [Appel, 1992, p. 228], and that *newer cells have a higher proportion of garbage, which is why the garbage collection efforts should be concentrated on them* [Appel, 1992, p. 208]. Both of these statements are true, but not in the same context. If the meaning of characterizations such as these is improperly or simplistically understood, it is easy to derive incorrect inferences.

for relatively young objects, the behavior for relatively older objects, and certainly for very long-lived objects in long-running programs, remains unexplored.

Concerning the second tenet, excess copying: we empirically examined the difference in copying cost between a collector that assumes that everything outside the collected region is live, and one that has an oracle to tell apart the live from the dead. For the collection schemes we considered, we found that, as long as the scheme preserves the objects in a logical order of allocation (thus always having data of a contiguous age group in the region collected), the excess copying is usually not excessive. We then measured the statistics of pointer direction and found that neither older-to-younger nor younger-to-older direction dominates across all studied traces (Smalltalk and Java). But, more importantly, we found that pointer distances (differences in age between the object containing the pointer and the object pointed to) are very small indeed, whether positive or negative.[2] While this property works in favor of generational collection, it also works in favor of any other age-order-preserving collection scheme, by reducing the number of pointers that must be maintained (Section 3.2.2).

Concerning the third tenet, the implementation overheads: it withstood our validation. Indeed, the circumstance that neither pointer direction dominates is not significant, in light of another empirical fact: most pointer stores are into new, or very recently allocated objects. Generational collectors do not need to record these stores, regardless of direction. The other age-based collectors we introduce here must record the younger-to-older pointer stores into new objects, and pay a significant price for it. Nevertheless, we shall see that for many programs, it is worth paying this price to receive the benefit of lower copying cost.

In this study, we explore generational and other collection schemes among those that preserve the relative order of objects, using simulation studies and a prototype collector imple-

---

[2]DeTreville reports that in Taos, an operating system written in Modula-2+, the younger-to-older pointer stores barely outnumber (by $1.96 \cdot 10^6$ to $1.17 \cdot 10^6$) older-to-younger pointer stores [DeTreville, 1990b, p. 29]. The reported temporal distances are also very short; since they were obtained with respect to a particular garbage collector execution, they are not directly comparable to our measurements of Smalltalk and Java distances in Section 6.2.

mentation. We examine the obvious opposite of youngest-first collection, which is a strict oldest-first: choosing a fixed amount of oldest data. It sometimes works well, but if the chosen amount is small, the collector works poorly. Similarly, a strict youngest-first collector, which always chooses a fixed amount of youngest data (i.e., the nursery), works poorly. These observations lead us to explore strategies in which the collector chooses the collected region more flexibly, and visits both older and younger regions. A deferred older-first collector does so in the simplest possible manner, by moving a window of collection across the heap, but looking at older objects first. It performs remarkably well, sometimes close to the performance of a locally-optimal collector. The intuitive reason for this good performance is also remarkably simple: as the window of collection moves towards younger objects, it finds itself eventually at a position corresponding to an age by which most objects have died; and, since few objects survive in the window, the window does not move very fast. Thus, this collector homes in on the region where it is most profitable to collect, and stays there for a long time. A welcome property is that the best configurations observed in our experiments are those with a small window size, and, since the amount copied per collection is limited by window size, the low total copying cost is accompanied by predictably short pause times. Pointer-maintenance costs are inevitably higher in this collector than they are in generational collection. Nevertheless, the trade-off between these two cost components favors the newly proposed collector for a number of programs we examine.

In Chapter 2, we present the state of scholarship and introduce the terms used in the study of garbage collection algorithms. We discuss a classification of age-based collectors and the design and implementation of new algorithms in Chapter 3. We set the stage for the experimental evaluation of different collectors by examining the intrinsic properties of benchmark programs in Chapter 4. The copying cost of collection is the subject of Chapter 5, while the pointer-maintenance cost is discussed in Chapter 6.

Note on organization. Chapters 4–6 include long series of figures and tables. These are printed *en masse* at the end of each chapter, so as not to disrupt the flow of text, yet keep them close to it.

CHAPTER 2

BACKGROUND

This chapter introduces the concepts and the terminology used in the subsequent discussion while surveying the vast field of literature related to memory management and garbage collection.

2.1 Dynamic memory management

Under the appellation of dynamic memory management, we study the provision in the run-time system of a programming language of mechanisms for allocation of contiguous blocks of memory of arbitrary size and unrestricted temporal extent at the request of the program. These blocks of memory are known as *objects*. In object-oriented languages, there is usually a one-to-one correspondence between a linguistic object and its representation as a dynamically allocated block of memory. In other contexts, the representations of a C `struct` created using a call to `malloc`, a Pascal record created using `new`, or a LISP `cons` cell, are all objects.

A significant amount of research has gone into algorithms for managing dynamically allocated data under the restriction that the objects must not be moved, and that the program must explicitly request object deallocation following its last use of an object. These algorithms concentrate on fast allocation, typically using free lists, and efficient memory usage, avoiding fragmentation. Wilson wrote an excellent survey of the field [Wilson *et al.*, 1995].

Our focus, however, is on algorithms that automatically detect that the last use of an object must have occurred, by proving that no further use of the object is possible. These algorithms

are called *garbage collectors*. They remove the burden of object deallocation from the programmer, and in so doing eliminate an important source of programming errors.[1]

The garbage collector considers an object to be garbage (or *dead*) if it is not *reachable*: the program cannot access it by any chain of pointer traversals. Any object that is potentially reachable is considered *live*. Although the name implies that garbage is collected, it is usually the live objects that the collector works with: it preserves them, while reusing the space of the garbage objects.

We shall briefly introduce the concepts needed to understand the arguments made later; for a comprehensive treatment, the reader should consult Cohen's survey of the early development of garbage collection techniques [Cohen, 1981], Wilson's survey, which concentrates on newer algorithms [Wilson, 1992], as well as Jones and Lins's textbook presentation of the field [Jones and Lins, 1996].

2.1.1 Liveness and reachability

Let us first look at simple (non-generational) collection, in which the entire heap is subject to collection. Ideally, any object that will not be used by the program after the time of collection can be discarded as garbage. Unfortunately, this criterion is not effectively computable. Instead, the consensus is to use *pointer reachability* as a conservative approximation. Given a set of root pointers into the heap, owned by the program in its data outside the heap (stack, registers, etc.), everything reachable from this set is considered live. In other words, the transitive closure of the points-to relation, starting with the roots, defines the survivors of the collection. This approximation is safe, since no computation can use an object unless it can refer to it by a pointer, and if it does not already have that pointer it can only obtain it by following some chain of pointers starting from some other pointer it does have. Pointer reachability is simple to compute and is found in the core of all garbage collectors. Between the approximation of

[1] A study of software errors in IBM MVS ascribes almost one half to pointer and array access errors [Sullivan and Chillarege, 1991].

liveness by reachability and the unachievable exact liveness according to future use, there can be a gradation of techniques to make the approximation more accurate using different static analyses of the program (compile-time garbage collection, live variable analysis, etc.). We do not consider these here; hereafter we equate liveness with reachability from the root set of pointers.

We are concerned, however, with another distinction that arises only with region-based collection, which divides the heap H into a collected region C and a remainder U. Live objects in the collected region are those reachable from the set of root pointers. The goal of region-based collection is to avoid having to look at the (normally large) remainder. Instead, a write-barrier ensures that all pointers crossing from U to C are readily available at time of collection. All such pointers, called the *remembered set* for region C, are added to the root set, and then the transitive closure of pointer reachability is computed only within C. Let us call this result S_r, for *survivors by remembered-set reachability*. The actual set of live data is $S \subseteq S_r$. Calculation using remembered-set reachability treats all objects in the uncollected remainder U as if live, since it does not examine U, and thus potentially overestimates the set S. In *any* region-based collector, there is potential for such excess retention or "nepotism" [Ungar and Jackson, 1988] on each garbage collection.

How much excess retention is there? Clearly, a collection scheme could have dramatically high amounts of excess retention if it were the case that (1) pointers tended to cross region boundaries predominantly into the collected region, thus there were many pointers in the remembered-set, *and* (2) many of these pointers were from objects in the remainder that are actually dead, *and* (3) the pointer structure caused the transitive closure operation falsely to mark very large amounts of data as live, starting from such false pointers. The effects on performance would be profound, since both the cost of each collection and the frequency of collections would be high.

We have assumed in the preceding that the set of external roots in the stack and registers is accurately known. This is predicated on the ability of the collector to examine and interpret

the stack and registers. A system may opt for self-descriptive data, which incurs the space overhead of tagging each word, or a more compact form using stack maps describing stack contents at admissible garbage collection points. Additionally, a data-flow liveness analysis may reduce the number of registers in the root set [Agesen *et al.*, 1998].

On the contrary, if the system is uncooperative, then it may be the case that neither the values in the stack and registers, nor the values in the heap can be accurately interpreted: it may be impossible to distinguish some pointer representations from some non-pointer representations. Such is the situation with languages such as C and C++, which were designed without garbage collection in mind. *Conservative* garbage collectors (or *ambiguous-roots* collectors) have been developed to cope with this problem [Boehm and Weiser, 1988; Demers *et al.*, 1990; Boehm, 1993]. Although the analyses in this study have been designed and experimentally tested with accurate-roots collection in mind, they may be adapted to an ambiguous-roots setting.

2.1.2 Preserving live data

The collector must preserve the live objects for future use by the program. However, a distinction is made in collector design among techniques that keep objects in place, and those that move them. Mark/sweep collectors do not move objects [McCarthy, 1960]. Instead, free lists are used to manage space, as in manual dynamic storage allocation. The mark phase automates the detection of objects that have become garbage, while the sweep phase invokes the deallocation routine of the underlying dynamic storage allocator for each garbage object in turn. Copying collectors, which are the focus of our study, move the live objects into a new memory area, the "to-space," allowing the entire old area, or "from-space," to be reused for allocation [Minsky, 1963; Fenichel and Yochelson, 1969]. The copying is accompanied by the update of pointers that point to the moved objects. The detection of live objects, by transitive closure for pointer reachability, and the copying into to-space are usually interleaved in a *Cheney scan* [Cheney, 1970] which also eliminates the need for an auxiliary stack to compute the closure. With the use of two *semispaces* allocation is from a contiguous area,

hence simple and fast. The collector visits only live objects, which are typically fewer than garbage objects. However, the memory requirement of the copying collector is, in the worst case, double that of the mark/sweep collector.

2.1.3 Incremental collection

Collectors that collect entire heaps at once incur very long pause times. In applications tolerating only short and predictable pauses, incremental collection is needed. The coordination between the collector and the running program to allow the collector to make progress piecemeal, or even concurrently with the program, is not simple. It is accomplished either using a *read-barrier* mechanism, or a *write-barrier* mechanism. With a read barrier, the program is alerted when it tries to follow a pointer to an object that the collector has moved [Baker, 1978]. Because read operations are extremely frequent, read barriers have used hardware support for efficiency [Zorn, 1989].[2] With a write barrier, when the program stores a pointer into an object, the write is recorded. Whereas hardware support for the write barrier can be provided as well, as in the SOAR Smalltalk system [Ungar, 1986], pointer update operations are typically much fewer in number than pointer reads, so a software barrier in the form of in-line code is generally thought to be acceptable.

2.1.4 Generational copying collection

Generational copying collection divides the heap according to the age of objects into multiple areas, or generations, and collects younger generations more frequently than older generations [Lieberman and Hewitt, 1983; Moon, 1984; Ungar, 1984]. There are subtle differences among these algorithms as described in the literature, because most descriptions combine the organization of the heap into generations with particular policies for promotion of survivors of garbage collections. Even when these algorithms are designed as non-incremental ("stop-and-copy"), they can be effectively incremental, by virtue of the fact that most collections are only

---

[2] Zorn finds that a software read barrier could be implemented with a CPU overhead of not more than 20%, however [Zorn, 1990a].

of the youngest generation, and thus most pauses are short. Numerous practical implementations and studies of predictive and adaptive management of generations have reported good performance [Caudill and Wirfs-Brock, 1986; Courts, 1988; Shaw, 1988; Sobalvarro, 1988; Ungar and Jackson, 1988; Wilson, 1989; Wilson and Moher, 1989; Appel, 1989b; Wilson *et al.*, 1991; Hudson *et al.*, 1991; Stefanović, 1993b; Stefanović and Moss, 1994; Diwan *et al.*, 1995; Barrett and Zorn, 1995].

The performance of a collector is affected by a number of factors: the number of generations in the system; the promotion policy, or how long an object must remain in one generation before it is advanced into the next older; when to initiate collection; and how to track the pointers from older to younger generations [Wilson, 1992]. This space of design choices is immense. Moreover, the allocation characteristics of languages and individual programs are varied, and they strongly affect the performance of collectors. The performance metrics—time overhead, pause time, and space overhead—are insidiously hard to define and measure. Does the time overhead include the write barrier, and how can the cost of the write barrier be extricated from other run-time costs? Is maximum pause time more important than average pause time, or some percentile of the distribution thereof? Should one measure the peak memory usage or the average memory usage? Should peak usage reflect the space needed only during copying to hold the to-space? Is it reasonable to let the oldest generation be "tenured" (allowed to grow indefinitely and never collected) or should measurements be taken with respect to a constant available space? The answers to these questions must depend on the intended application. As a result of the inherent complexity of generational collector design and of the methodological difficulties in evaluation, the understanding of generational garbage collectors has remained incomplete.

Aside from remarks in Wilson's survey [Wilson, 1992] and Jones and Lins' book [Jones and Lins, 1996, p.151], which admit the possibility of collecting an older generation independently of a younger one, generational collectors are youngest-first: when collecting an older generation, all younger ones must also be collected. The number of generations is typ-

ically small, so the choice of the size of the collected region is limited. Barrett and Zorn examined an adaptive scheme which dynamically chose an age boundary for each collection [Barrett and Zorn, 1995]. Our work instead proposes to collect among older (but not necessarily oldest) objects preferentially, postponing the youngest objects until they have had time to become older and die. The work closest to ours in this respect is Clinger and Hansen's "non-predictive" collector, which organizes objects according to the time elapsed since last collected and performs well with a hypothetical exponential distribution of lifetimes [Clinger and Hansen, 1997]. However, as we shall see in our empirical study in Chapter 5, that particular organization does not work remarkably well.

2.1.4.1 Pointer maintenance

In order to collect one region (a set of youngest generations) without collecting the remainder of the heap, the set of pointers crossing the boundary from the remainder and into the collected region must be known. Pointers installed in an object at the time of its creation can only point to older objects and can never cross the boundary in the interesting direction, only pointers installed by *updates* can. Each updating pointer store must be checked: if the stored pointer is $p \to q$, and p is in an older generation than q, then a record of this store will allow the pointer to be found at the time of collection of q. Early generational collectors used indirect pointers and region entry and exit tables, mechanisms that are very expensive without hardware support for pointer operations, and not transparent to the language. Ungar's collector used a *remembered set* of updated objects in the old (tenured) generation [Ungar, 1984]. A set can alternatively record the precise location of the updated object fields ("slots"), trading extra space for reduced time to find the updated fields at garbage collection time [Hosking *et al.*, 1992]. If there are few repeated stores into the same location between collections, a data structure simpler than a set may be preferable, such as a store list [Appel, 1989b] or a sequential store buffer [Hosking *et al.*, 1992].

Virtual memory mechanisms can be used to record the approximate location of updated object fields to within a page. Pages are write-protected, the first update of a page causes a page protection fault, and the software fault handler makes a note of the page (in an auxiliary bit array) and unprotects it. This scheme is called *page marking*. Unfortunately, virtual memory primitives in current operating systems are not well adapted to the task (non-pointer stores and null pointer stores equally cause protection faults) and are slow (because of user/kernel mode switching) [Zorn, 1990a]; moreover, the granularity of pages is too coarse (the ratio of page size to the typical number of pointer updates within it is high) [Hosking *et al.*, 1992]. Software surrogates of page marking are known as *word marking* [Sobalvarro, 1988], or more generally, *card marking*, in which the address space is conceptually divided into sub-page units (cards). Each pointer store is augmented with code to index into an auxiliary card table and set the bit corresponding to the card of the updated field. Whereas word marking records the precise location of updated fields, card marking with cards larger than a word saves auxiliary table space at the cost of scanning individual cards at garbage collection time [Hosking *et al.*, 1992]. Card tables as described tend to retain scattered marked entries over time, and it is better to summarize them at collection time (into a concise remembered-set representation) so that the card table reflects only incremental updates [Hosking and Hudson, 1993].

2.1.5 Mature spaces

Bishop [Bishop, 1977] and later Hudson and Moss [Hudson and Moss, 1992] proposed dividing the heap into spaces managed by different algorithms. Bishop allows several independent areas, not necessarily all garbage-collected, and uses lists of incoming and outgoing inter-area links. Hudson and Moss divide the heap by age into a young and a mature space, which is in agreement with the intuition that the patterns of pointer structure linking the objects lose the strong directional bias (see Section 6.2) after a certain age, hence the generational algorithms, which exploit this bias, lose efficiency. The mature space is divided into areas of bounded size (or blocks of fixed size in an implementation in the Beta language [Grarup and

Seligmann, 1993]), which are processed one at a time. It is assumed that a generational algorithm manages the young space and engages the incremental mature space algorithm only when promoting out of the oldest generation of the young space.

2.2 Object survival and mortality

A recent book on garbage collection states [Jones and Lins, 1996, p.144]:

> *The insight behind generational garbage collection is that storage reclamation can be made more efficient and less obtrusive by concentrating effort on reclaiming those objects most likely to be garbage, i.e., young objects.*

Hayes and others observe that youngest objects have the highest *mortality* [Hayes, 1991; Baker, 1993; Hayes, 1993; Stefanović and Moss, 1994], which is a refinement of the somewhat vague observation that most objects have a very short lifetime while some live much longer [Lieberman and Hewitt, 1983; Ungar, 1984; Shaw, 1988; DeTreville, 1990a; Zorn, 1990b]. Figure 2.1 graphs a typical mortality function using Tomcatv written in Smalltalk as an example (see Section 4.2.2.3), with the age of objects on the horizontal axis, and for a given age, the rate at which they die on the vertical axis. Both axes use a logarithmic scale.

Is high mortality the same as being most likely to be garbage? No, since the very newest objects are patently not garbage. In statistical terms, it is the *survivor* function, and not the mortality, that tells us what is live, and the survivor function is always 1 at age 0. Formally, the survivor function $s(t)$ is the fraction of original allocation that is still live at age t. The mortality $m(t) = -\frac{s'(t)}{s(t)}$ is the age-specific death rate, or likelihood that an object will die in the next instant provided it has survived until age t [Cox and Oakes, 1984; Elandt-Johnson and Johnson, 1980; Baker, 1993]. Figure 2.2 plots a typical survivor function, again using Tomcatv. The horizontal axis is object age on a logarithmic scale. The vertical axis is the fraction of original allocation still live at a given age.

Given a region of just-allocated data of size V, is it more profitable to collect its younger half, ages 0 to $V/2$, or its older half, ages $V/2$ through V? Statistically speaking, the answer

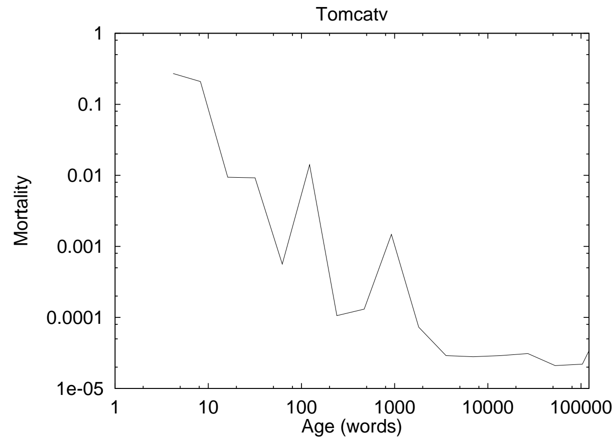

Figure 2.1. A typical object mortality function.

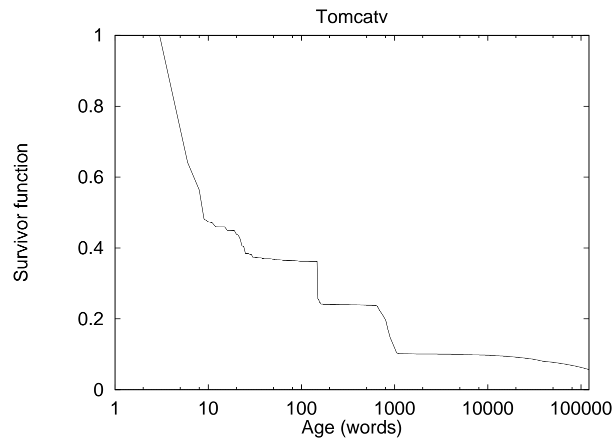

Figure 2.2. A typical object survivor function.

must be to collect the older half, which is clear from the survivor function diagram, Figure 1.1, or the simple calculation: $\int_{V/2}^{V} s(t)dt \leqslant \int_{0}^{V/2} s(t)dt$, because the survivor function $s(t)$ is non-increasing.

In practice, we have to decide where to put the survivors, which complicates this simple analysis. The analysis suggests, however, the following revision of the preceding quotation:

> *Generational collection is efficient, provided its generations are well configured, because it concentrates on a set of young objects that includes the objects most likely to be garbage, albeit along with objects least likely to be garbage.*

If the collector can concentrate *only* on the objects most likely to be garbage, then it may be able to achieve even lower copying cost. This discussion was entirely independent of the

actual shape of the survivor and mortality curves, but the relative merits of generational and other collectors will certainly depend on them.

Assumed or measured object lifetime distributions can be used to predict the performance of collectors [Clinger and Hansen, 1997]. However, the implicit assumption that object lifetimes are independent identically distributed random variables is far from true: phase behavior of programs must lead to highly correlated object lifetimes. The collector performance calculations are tied to the assumption of a steady state, but this assumption restricts the class of admissible distributions. The questions of the feasibility and the utility of analytical modelling of object lifetimes therefore remain open [Stefanović *et al.*, 1998a; Appel, 1997; Stefanović *et al.*, 1998b].

2.3 Theoretical models of memory management

Object-based computation appears in its purest form in the Storage Modification Machine, or pointer machine [van Emde Boas, 1990; Kolmogorov and Uspenskii, 1958; Schönhage, 1980], a model of computation based on a finite directed graph structure of storage instead of an array of memory registers as in the more commonly used RAM model. The graph structure is dynamic. The model incorporates the notion of new node creation. The requirement for what we call garbage collection is expressed abstractly in the following dictum [van Emde Boas, 1990, p. 32]: "The map p^* does not have to be surjective; however, nodes which can not be reached by tracing a word w in Δ^* starting from the center a will play no subsequent role during the computations of the SMM, and therefore nodes may be assumed to have disappeared when they become unreachable."

A complementary aspect of theoretical approaches is the development of semantic models of memory management: deriving the properties of dynamically allocated data by linguistic means, usually in the context of typed functional languages [Morrisett *et al.*, 1995]. These models indicate which objects are garbage and why, and additionally allow one to express memory management actions syntactically, and then reason about their correctness. (Unfor-

tunately, these models do not answer quantitative questions of the kind posed in our study.) Similar models are desirable for memory management in object-oriented languages, but their semantic modelling in general remains less settled [Abadi and Cardelli, 1996]. A related discipline is that of compile-time garbage collection, or type and data-flow analyses to improve the run-time performance of collection in (usually) functional languages [Appel, 1989a; Harrison, 1989; Baker, 1990; Goldberg and Gloger, 1992; Boehm and Shao, 1993; Fradet, 1994; Aditya *et al.*, 1994; Mohnen, 1995]. The primary idea is to eliminate the need for heap allocation in the first place, by proving that certain objects can be allocated on the stack instead, which is considered (although not universally, cf. [Appel, 1987]) to be faster. More ambitious analyses aim to provide hints to a generational collector about object lifetimes [Yi and Harrison, 1992].

CHAPTER 3

AGE-BASED GARBAGE COLLECTION ALGORITHMS

In this chapter we establish a classification of garbage collection algorithms that preserve the age ordering of objects in the heap. We introduce new algorithms within this classification. Unlike generational algorithms, the new algorithms do not always collect a youngest subset of heap objects. We proceed to discuss the repercussions of this design difference on the implementation of copying and pointer maintenance in the collector.

3.1 Conceptual design

The garbage collection algorithms we consider are all "generational" in the broadest sense of the word: when a collection happens, each scheme partitions the heap H into two regions: the collected region C, in which the collector examines the objects for liveness, and if live, they survive the collection; and the uncollected remainder region U, in which the collector assumes the objects to be live and does not examine them. The non-generational collector is a degenerate case in which the latter region is empty. The collector further partitions the set C into the set of survivor objects S and the set of garbage objects G, by computing root pointers into C and the closure of the points-to relation within C. To make the freed space conveniently available for future allocation, a copying collector manipulates the survivors S by moving them to the "to-space". This manipulation is a primary cost of collection [Jones and Lins, 1996].

Denoting by $\|X\|$ the total volume of objects in a set X, we use as a measure of the copying cost of collection the "mark/cons"[1] ratio, the ratio of the volume copied to the volume freed (i.e., available for allocation in the subsequent cycle): $\mu = \frac{\|S\|}{\|G\|}$.

It is desirable to minimize μ. If the initial partition into C and U is such that most of C falls into G, the copied volume of survivors $\|S\|$ will be small. However, if *arbitrary* schemes are considered, then clearly the best scheme is one that always makes the initial partition so that $G = C$, and thus $\mu = 0$. But is it realistic? The computational effort to perform the initial partition ideally is as great as to perform a non-generational collection—except if an oracle were available. We consider as realistic only those schemes which compute the initial partition very cheaply.

We restrict our attention to a class of schemes that keep objects in a linear order according to a certain *object timestamp*. Imagine objects in the heap as if arranged from left to right, with the oldest timestamp on the left, and the youngest timestamp on the right, as in Figure 3.1. The region collected, C, is restricted to be a contiguous subsequence of this sequence of heap objects, thus the cost of the initial partition, simply choosing the two boundaries, in some prescribed manner, is virtually nil. We call these schemes *age-based* collection.

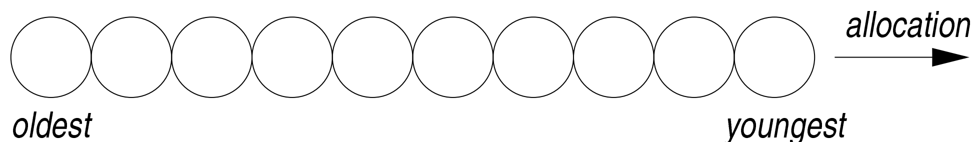

Figure 3.1. Viewing the heap as an age-ordered list.

We consider two notions of timestamp: *true age* and *renewal age*. In the first case, each object is given a permanent timestamp once, at the time of allocation. The relative order of objects in the sequence of heap objects never changes. In the second case, upon collection, the collector gives all survivors fresh, renewed, timestamps, as if they were newly allocated. It then moves these survivors to the young end of the sequence of heap objects.

[1]The name is used for historical reasons: in the original mark/sweep collector for LISP [McCarthy, 1960] the live objects were *marked* during collection, whereas the allocation consisted solely of LISP pairs, known as `cons` cells.

True-age timestamps permit the collector to focus attention on particular age groups, i.e., on sets of objects allocated consecutively. They arise naturally from considerations of object lifetime behavior—clusters of objects allocated together tend to expire together [Hayes, 1993]. On the other hand, the notion of renewal-age timestamps can arise from considerations of an *a priori* exponential lifetime distribution [Clinger and Hansen, 1997].

Traditional generational collection schemes are, in the main, age-based. They are based on true age, and the region collected is some subsequence that always includes youngest (most recently allocated) objects.[2] In the following, we introduce and categorize alternative collection schemes according to their choice of objects for collection. The age-based collection algorithm is also presented in the form of code in Figure 3.2.

3.1.1 True-age schemes

The simplest age-based collector and the base point of our comparisons is the non-generational collector. It will be labelled NONGEN in the discussion and figures below. The region of collection in NONGEN is always the entire heap: $C = H$, $U = \emptyset$.

We now consider age-based schemes, distinguished by different choices they make for the collected region. A *true youngest-first* (TYF) collector always chooses some youngest (rightmost) subsequence of the sequence of heap objects (Figure 3.3).

Generational collector schemes are variants of true youngest-first collection, differing in the size of C and in how they trigger collections [Barrett and Zorn, 1995]. In the basic design [Jones and Lins, 1996, p.147], new allocation is into one fixed-size part of the heap (the *nursery*), and the remainder is reserved for older objects (the *older generation*). Whenever the nursery fills up, it is collected, and the survivors promoted to the older generation (Figure 3.5). When the older generation fills up, then the following collection collects it together with the

[2]A slight divergence from the age-based criterion may arise in *copying* collectors, because the order of the objects in to-space is determined by the heap traversal (typically breadth-first, as in the standard Cheney scan [Jones and Lins, 1996; Cheney, 1970]), and is in general different from original order in from-space. Hence, the age order of objects is perturbed slightly within S for each collection. In *compacting* collectors reordering does not occur at all.

```
initialize:
    available_space := heap_size
    current_timestamp := 0
allocate (num_words):
    if available_space ⩾ num_words then
        create new object o with
            o.size := num_words and o.timestamp := current_timestamp
        current_timestamp := current_timestamp + num_words
        available_space := available_space - num_words
    else
        Garbage collection:
        set timestamp boundaries t_min, t_max according to scheme
        C := {o|o.timestamp ∈ [t_min, t_max]}
        U := H \ C
        S_0 := {o|o ∈ C ∧ (∃r ∈ Roots ∪ U) r → o}
        S := TC(→, C, S_0), where transitive closure is computed as:
            S_n = {o|o ∈ C ∧ (∃o' ∈ S_{n−1}) o' → o}
            S = ⋃_{n=0}^{∞} S_n (union finite)
        G := C \ S
        available_space := available_space + ||G||
        discard objects in G
        if ||G|| = 0 then fail
    fi
```

nursery. In a two-generation collector, that collection considers the entire heap. The collector deliberately reserves space, so that, unlike in TYF, the region chosen for collection contains exactly the objects allocated since the last collection (except for full heap collections). The operation of the GYF collector is summarized in the code of Figure 3.4.

We study two- and three-generation schemes: 2GYF (2 Generations; Youngest-First), and 3GYF. We stipulate that the size of each generation is strictly greater than 0, and therefore 3GYF never degenerates into 2GYF. When discussing generational schemes generally, we use the label GYF. We also examine a scheme in which the older generation is allowed to grow and use all the space of the nursery, and vice versa [Appel, 1989b], and no space is held in reserve; this scheme is denoted NGYF, and its operation is shown in Figure 3.6.

The simplest youngest-first collector is one that always chooses a constant amount of youngest objects to collect; we call this scheme FC-TYF (Fixed size of Collected region; True Youngest-First). Note, as is clear from the diagram in Figure 3.7, that survivors of the preceding collection remain in the collected region. One can expect this collector to be inefficient,

initialize:

Generations 1–N:

set $\sum_{g=1}^{N} nominal_size_g = heap_size$

for $g = 1,\ldots,N$ do $Gen_g := \emptyset$

$reserve := heap_size$

$next_gen := 1$

allocate (*num_words*):

if $\min(nominal_size_1 - current_size_1, reserve) \geqslant num_words$ then

create new object o in Gen_1 with

$o.size := num_words$

$current_size_1 := current_size_1 + num_words$

$reserve := reserve - num_words$

else

Garbage collection:

$gen := next_gen$

$C := \bigcup_{g=1}^{gen} Gen_g$

$U := H \setminus C$

$S_0 := \{o | o \in C \wedge (\exists r \in Roots \cup U) r \rightarrow o\}$

$S := TC(\rightarrow, C, S_0)$

for $g = 1,\ldots,gen$ do $S^{[g]} := S \cap Gen_g$

$Gen_1 := \emptyset$

for $g = 2,\ldots,gen{+}1$ do $Gen_g := Gen_g \cup S^{[g-1]}$,

except if $gen = N$ then $Gen_N := S^{[N]} \cup S^{[N-1]}$

$reserve := heap_size - \sum_{g=1}^{N} \|Gen_g\|$

$next_gen := \min g' : (\forall g \geq g') \|Gen_g\| \leqslant nominal_size_g$

fi

Figure 3.4. Pseudocode for GYF collectors.

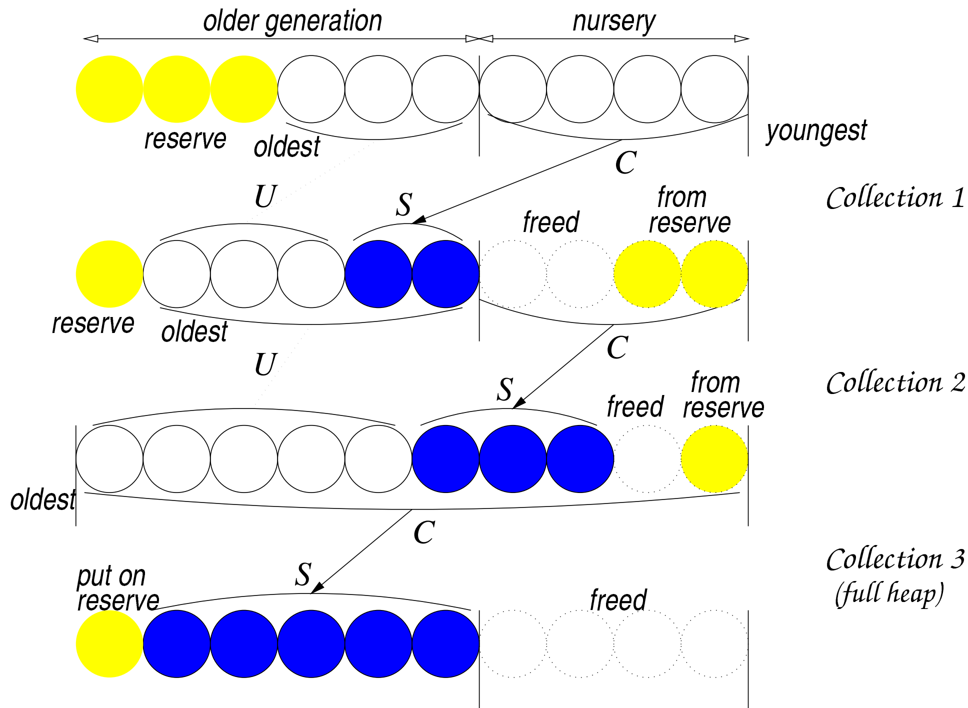

Figure 3.5. Generational youngest-first collection (2GYF).

because objects are repeatedly copied, and collections are frequent, because only the space freed is available for new allocation. Indeed, the older region remains untouched after it is initially allocated. Contrast this with the GYF collector, which does not use all the available space, putting some on reserve, but is then able to collect at regular intervals that correspond to the nursery size, and does not copy survivors of minor collections again until the next full collection.

A *true oldest-first* (TOF) collector always chooses an oldest (leftmost) subsequence of the sequence of heap objects (Figure 3.8). An FC-TOF collector considers a constant amount of oldest objects. It is clear that survivors of the collection will be collected repeatedly. If the oldest objects in the heap survive indefinitely, as in many programs, and the collected region is small and only encompasses such objects, FC-TOF necessarily fails because it finds no garbage in the collected region. However, we encountered some programs where FC-TOF, with a moderate size of the collected region, works better than other age-based collectors: intuitively, it gives objects enough time to die before they enter the collected region.

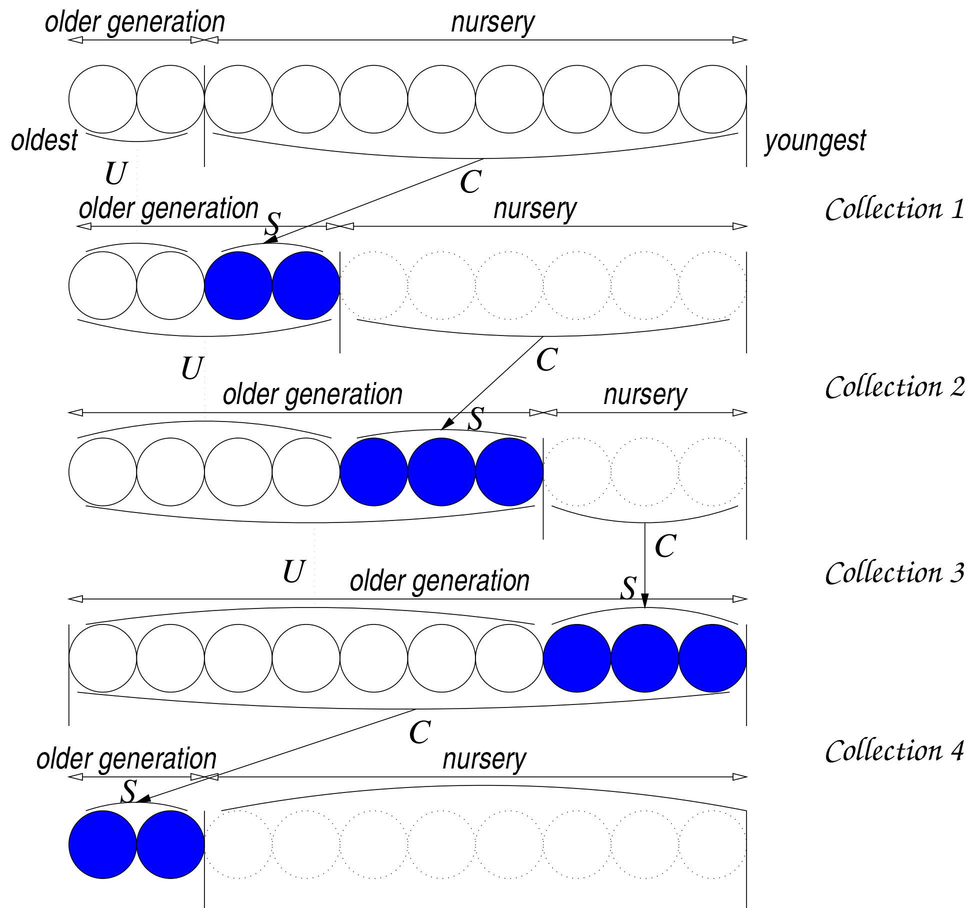

Figure 3.6. Generational youngest-first collection with flexible generation boundaries (NGYF).

The simplicity of FC-TYF and FC-TOF schemes is in the fact that collected regions are fixed. However, it is intuitively clear that performance suffers because some objects are subjected to collection repeatedly, while others are not subjected to collection soon enough. Thus, we must look for schemes that consider all parts of the heap at appropriate intervals. Note that GYF, which is known to work well in practice, revisits the entire heap, and at regular intervals, by means of full collections. Let us instead examine ways to revisit all of the heap piecemeal.

A *deferred older-first* (DOF) collector chooses a middle subsequence of heap objects, which is immediately to the right of the survivors of the previous collection (Figure 3.9). Thus the region of collection sweeps the heap rightwards, as a sliding window of collection. If the remaining area to the right is smaller than the window, the collector completes the sweep by

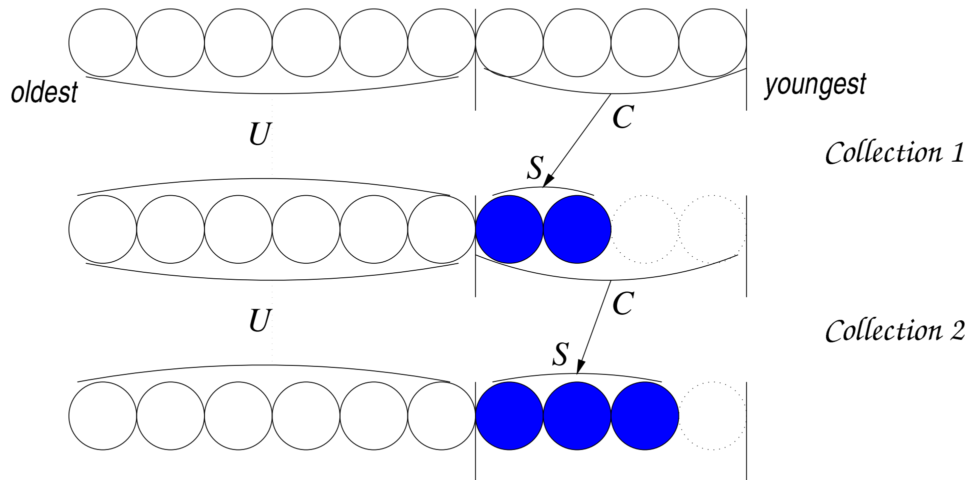

Figure 3.7. FC-TYF: True youngest-first collection (fixed collected region).

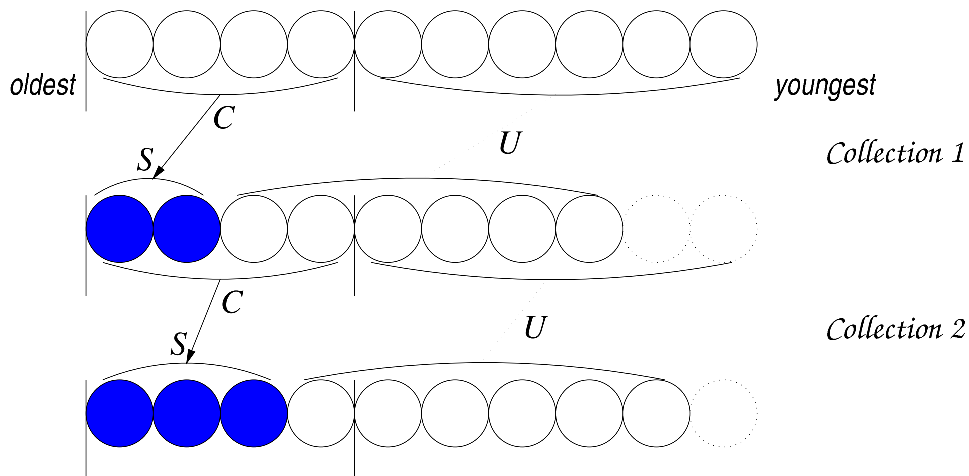

Figure 3.8. FC-TOF: True oldest-first collection (fixed collected region).

collecting the remaining area of youngest objects.[3] The FC-DOF collector employs a window of constant size.

The intuition for the potentially good performance of the FC-DOF collector can be gleaned from the diagram in Figure 3.10, which shows a series of eight collections, and indicates how the window of collection might move across the heap. The most important aspect is that if the window is in a position that results in small survivor sets, then the window moves by only a

[3]In the original description of the DOF algorithms, we proposed that as soon as the remaining area to the right is smaller than the window, the window is reset to the left end. However, we subsequently found that better worst-case copying cost is achieved with the current description. Additionally, full sweep is required for certain pointer filtering techniques (see below, Section 3.2.2).

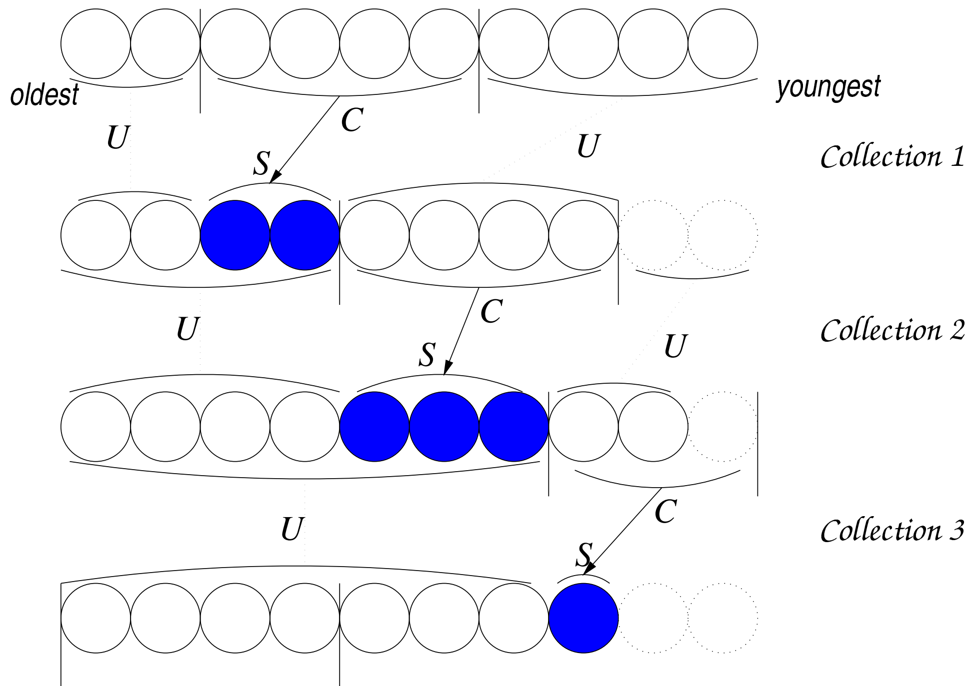

Figure 3.9. FC-DOF: Deferred older-first collection.

small amount from one collection to the next. If it continues to move slowly, then it is likely to remain for a long time in the same region, corresponding to the same age of objects, and it continues to enjoy small survivor sets (Collections 4–8). The outcome is that considerable progress is made in allocation while but a small amount is copied: μ is low. The question then is how long the window can remain in such a good position, and, once it has left it, how costly is the return, which involves finishing the rightward sweep, resetting to the left end, and sweeping over older objects back to the "sweet spot."

A *deferred younger-first* (DYF) collector similarly sweeps the heap, but leftwards (Figure 3.11). As soon as the remaining area to the left is smaller than the window, the window is reset to the right end. The FC-DYF collector employs a window of constant size. Despite the apparent symmetry of definition, DYF does not enjoy the window-motion benefit of DOF: the window moves leftward by one window size even when there are no survivors. We shall find that for this reason DYF never performs well.

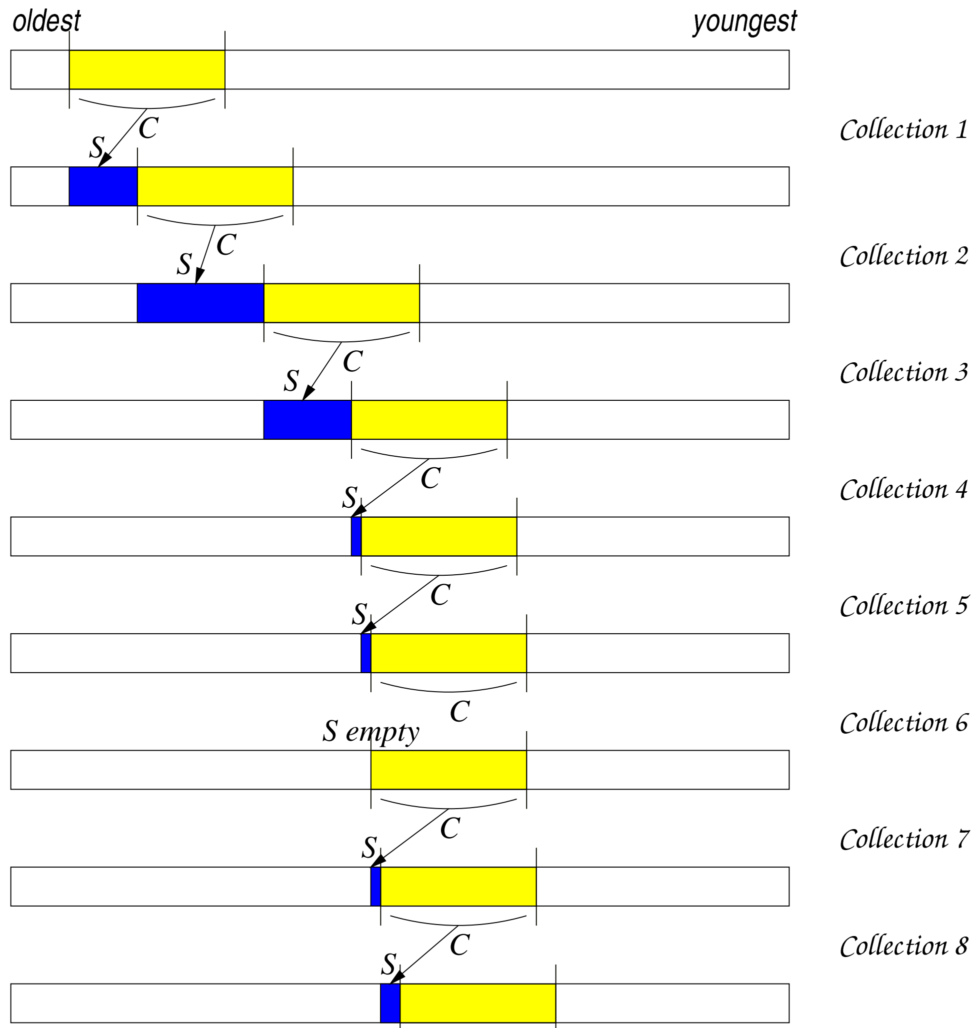

Figure 3.10. Deferred older-first collection, window motion example.

3.1.2 A renewal-age scheme

The collector proposed recently by Clinger and Hansen [Clinger and Hansen, 1997] and its generalization, the "oldest-first" collector [Stefanović *et al.*, 1998a], are also age-based, but according to renewal age, and older objects form the collected region. Similar ideas for circular management of heaps can be traced to earlier literature [Baker, 1978; Bekkers *et al.*, 1986; Lang and Dupont, 1987]. A *renewal-oldest-first* collector always chooses a leftmost subsequence of the sequence of heap objects—but the survivors are placed to the right of the uncollected remainder (Figure 3.12). Therefore, even though the collection window remains at the left, "old" end, the collector does not process the survivors of the collection again, until

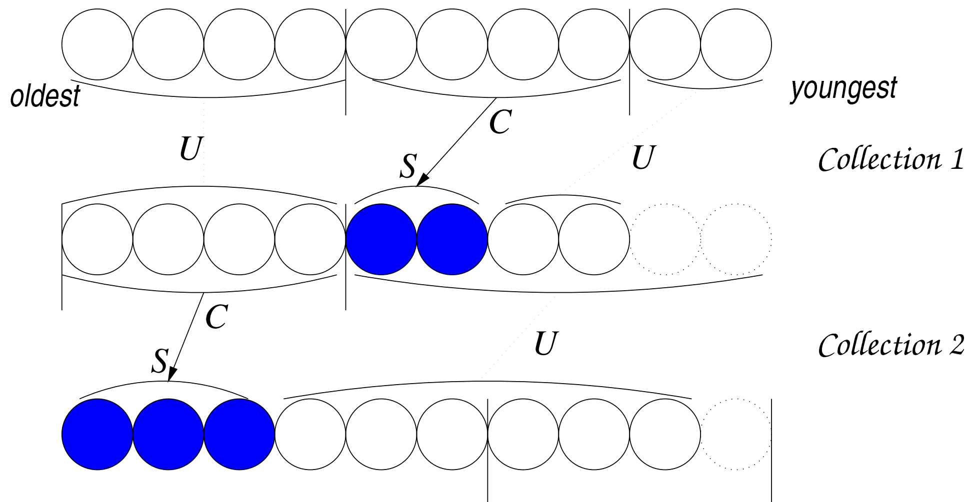

Figure 3.11. FC-DYF: Deferred younger-first collection.

they have been pushed back to the left by new allocation after several succeeding collections. Note, however, the conspicuous crossover of the logical paths of survivor and remainder objects, which results in irreversible mixing of true object ages in the heap, even in compacting collection.

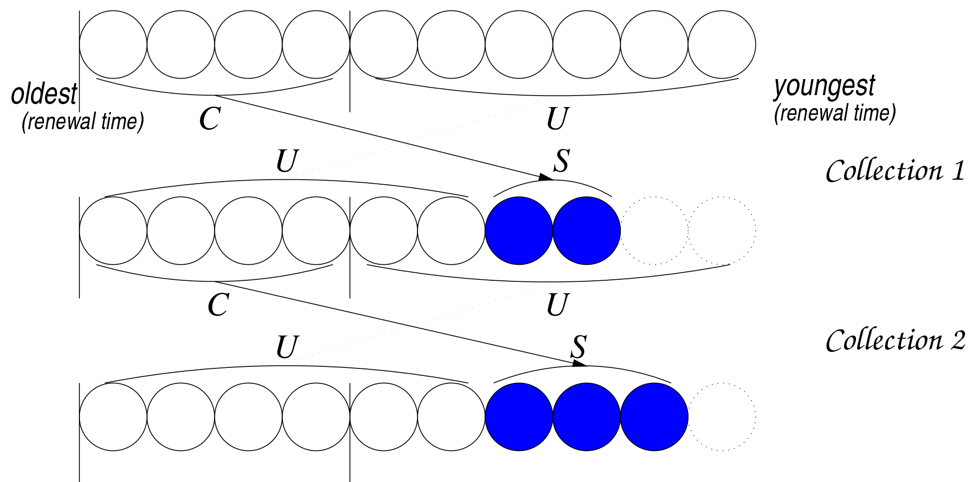

Figure 3.12. FC-ROF: Renewal-oldest-first collection.

3.1.3 Towards optimal schemes

There is a final category of schemes, clearly unrealistic for actual implementations, that we consider. Recall that a deferred oldest-first collector collects a middle subsequence of

age-ordered heap objects. Contemplate for a moment a generalization: let us choose any subsequence of a given size, not necessarily starting from a known point, but instead whichever subsequence yields the lowest mark-cons ratio on this collection. Thus we arrive at the *locally-optimal* collector scheme FC-OPT.[4]

Is there a globally optimal scheme? The global optimum need not coincide with the aggregate outcome of locally optimal decisions. The overall copying cost can be reduced by selecting the amount of garbage released in such a way that the next collection comes at a particularly propitious time, namely when there are few live objects. However, the consideration of globally optimal schemes is beyond the scope of this investigation. Instead, we shall only use the results of the locally-optimal collector schemes as an upper bound on the minimum copying cost, for comparisons with realistic schemes.

3.1.4 Collection failure and recovery

It is possible, especially for an FC collector with a small setting for C, to find no garbage in the collected region. If that happens, we let the FC collector fail for the purposes of this study. An implementation could increase the heap size temporarily, or retry collection on another region. A moving-window scheme can retry collection at the next window position. Alternatively, the whole heap can be collected. Note that GYF schemes by design occasionally consider the whole heap, hence they enjoy an advantage over the FC schemes as simulated here, with the disadvantage that their maximum pause times are no lower than with non-generational collection.

3.1.5 Garbage cycles

A cycle of garbage objects can be so large that it cannot fit in the collected region. Even if the cycle is smaller than the size of the collected region, it can consist of objects of sufficiently

[4]Similarly, we could explore the limits of true oldest-first and true youngest-first collection: instead of fixing the amount to be collected, let the collector choose that amount which results in the lowest mark/cons ratio μ *for the current collection*, but we leave this exploration for future work.

diverse age that it is never entirely within the collected region.[5] In either case, the cycle cannot be reclaimed. Traditional generational collection, at the risk of long pause times, finds such cycles by collecting the whole heap occasionally. Since the presence of such cycles is liable to lead to poor performance and ultimately failure, the same remedy, suggested in the preceding section, applies. Alternatively, the purely age-based scheme can be modified, with provisions similar to the train algorithm for the *mature object space*, which tackles the problem of cycles while maintaining incrementality [Hudson and Moss, 1992; Seligmann and Grarup, 1995]. Note that the results presented here are based on a simulator and a prototype implementation which do not implement any mechanism to enforce reclamation of cycles.

3.1.6 Locality

Our study is based on extensive simulations, in order to explore a large number of collector configurations, and indeed a number of altogether different schemes. This focuses attention on the primary costs, namely copying and pointer maintenance. However, we cannot measure certain other costs, without integrating our implementation with a live object system. The chief of these costs is the effect on locality [Zorn, 1991; Reinhold, 1993; Gonçalves, 1995; Diwan *et al.*, 1995; Appel and Shao, 1996]. The schemes that we found to perform well with respect to copying cost also share the property that they *do not change* the relative order of objects; think of them as compacting. Therefore, they do not adversely affect the locality of access within the mutator. Unlike traditional generational collection, which repeatedly collects from the same memory region of young objects and *occasionally* the whole heap, some of the proposed schemes visit different parts of the heap more regularly. Although it is tempting to predict the memory hierarchy behavior of these schemes by observing the patterns of collected region motion, the complexity of interaction of allocation, copying and pointer maintenance

[5]This scenario is made unlikely by the fact that an unreclaimed cycle of garbage objects migrates to and concentrates in the oldest end of the heap. There its adverse effect on collector performance is indistinguishable from that of truly live but permanent objects (Section 5.4.3).

accesses with the memory hierarchy requires that the behavior should be measured in a fully implemented system instead.

3.2 Implementation

In preceding sections, we outlined several age-based garbage collection algorithms that we use to explore reducing copying cost beyond generational youngest-first collectors, by prescribing which portions of the heap should constitute the collected region. The following chapter will show that the promise of the DOF collector is actually delivered, but now we consider how to implement in practice a collector with a collected region that ranges outside the space of youngest objects.

If we look at all the age-based schemes together, we find two requirements for implementation. First, it must be possible to identify any set of objects according to their age, and use it as the collected region. Second, it must be possible to enumerate pointers into the collected set from outside, in order to collect it correctly.

3.2.1 Blocks

The first requirement can be fulfilled efficiently by dividing the heap into blocks and linking blocks into an age-ordered list (Figure 3.13). The collected region must consist of a number of blocks. This restriction on the freedom to choose the collected region is acceptable: constant overheads of collection will surely render too expensive any scheme that chooses extremely small collected regions. Therefore, imposing a block as the minimum size of the collected region, as well as the measure of granularity of window positioning, must be appropriate for some block size.

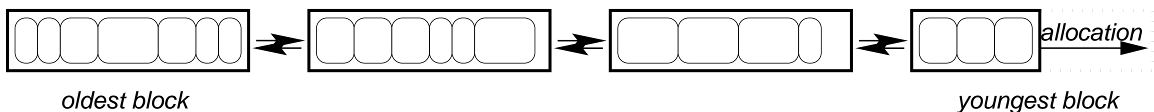

Figure 3.13. Heap organized as an age-ordered list of blocks.

Hence, the heap address space is divided into blocks. Each block consists of 2^b bytes, and is aligned on a 2^b-byte boundary. Assume for the time being that no object is larger than a block. Each object is entirely contained within one block.

The block table is an auxiliary data structure, an array that lists all the blocks available in the address space and records the status of each (free, or in use). Additional information for blocks in use is accessed indirectly, to avoid the space overhead for unused blocks.

Given the address of a heap object, or a field within an object, a constant b-bit-shift operation calculates an index into the block table corresponding to the block in which the object lies.

Blocks in use are doubly linked in age order, so that age-based collectors can easily follow their collection policies. Each block records the next free address within it, so that objects can be added to it: by the mutator in allocation, or by the garbage collection in survivor copying. During collection, each block records whether it is in the collected region or not. During the Cheney scan phase of garbage collection, a block also records the next address to be scanned. In generational schemes, the block additionally records the number of the generation to which it belongs.

The stipulation that whole blocks are subject to collection raises concern about possible fragmentation: if the survivors from an entire collected region must be placed in blocks themselves, then we can expect, on average, half a block of wasted space. The situation is easily remedied for the DOF collector, if the collector promotes survivors into any available space in the adjacent block to the left (youngest among uncollected blocks older than the collected region), as shown in Figure 3.14. Because of the rightward sweep of the collected region, any incomplete block left at the the end of one collection is filled in subsequent collections, and fragmentation is eliminated.

Objects larger than one block are allocated in a special area, the *large object space*, but each large object is logically assigned to a block. The collector never physically copies large objects, but rather logically moves them from a particular block to another by manipulating

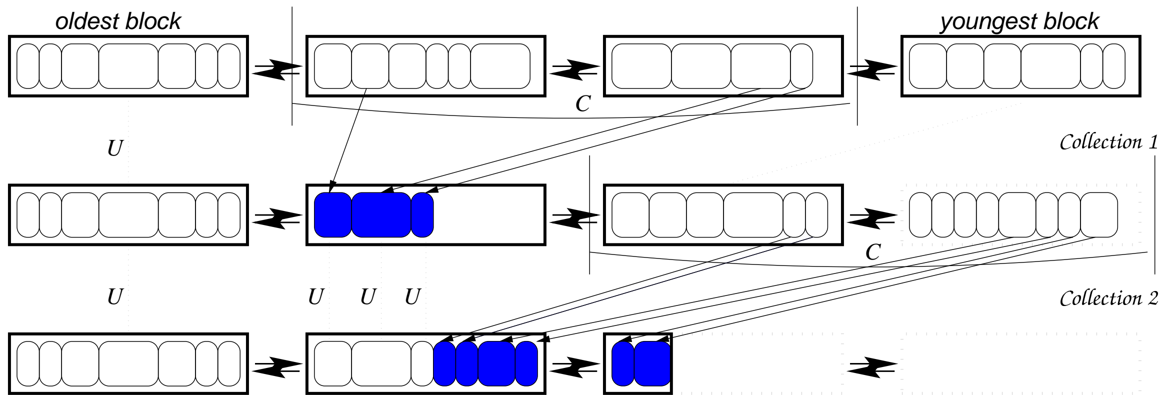

Figure 3.14. Filling preceding block to avoid fragmentation.

efficient indexing data structures. The implementation of large object space can be adapted from the one in the GC Toolkit [Hudson *et al.*, 1991]. The handling of objects in large object space is more expensive than of those in ordinary blocks [Hicks *et al.*, 1998]; an examination of the size distributions of objects (Section 4.2.3) shows, however, that large objects are a rare occurrence for our benchmarks.

3.2.2 Remembered sets

The second requirement is to be able to find pointers into the collected region, no matter which blocks, or how many blocks, are in the region. The most general solution is to track the set of pointers into each block (the remembered set), and then compute the union of the sets for all blocks in the collected region.

In contrast, note that a garbage collection algorithm that defines fixed boundaries for the collected region can safely record just the pointers that cross that boundary. For instance, a generational collector maintains one remembered set per generation, no matter how large the generation is. The need to maintain remembered sets for each block can cause significantly larger space overhead, as well as time overhead for recording and processing the pointers.

The generational collector does not even maintain truthful remembered sets for each generation: by design, a collection of generation n always collects all younger generations as well,

therefore it is only necessary to know the pointers into generation n from *older* generations.[6] As we shall see in Section 6.1.3, this structure greatly reduces the number of pointers that must be tracked.

Therefore, while the design using per-block remembered sets achieves the desired functionality for the fully-general age-based schemes, we must also consider the implications of the particular age-based scheme on the sets of pointer stores that the system can safely ignore.

Note that the majority of stored pointers have the source and target within the same block, as we shall see in Section 6.2. Since a block is always entirely within the collected region, or entirely outside it, such local pointers do not need to be recorded in the remembered sets. This optimization applies to all age-based schemes. It eliminates a majority of pointer stores for reasonable block sizes at very low cost.

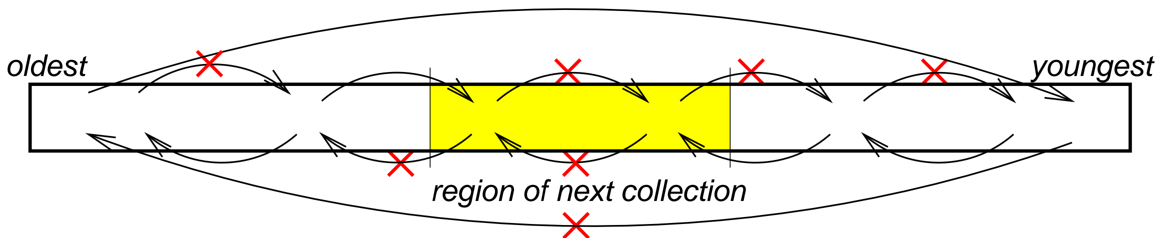

Figure 3.15. Directional filtering of pointer stores at run-time (DOF).

A more aggressive elimination criterion is possible. Suppose that the stored pointer is $p \rightarrow q$, and that the object p is subject to collection *before* object q. Then the pointer will be invalidated before q is collected, either because p is moved if live, or because p is dead. Hence the pointer $p \rightarrow q$ should not be recorded in the remembered set of q. Thus the general rule is to filter out those stores for which the source will be collected before the target, or at the same time as the target. Some age-based schemes have strict policies for the positioning of the collection window in the heap, and it is therefore possible to establish whether the source or the target of a pointer store will be collected first. Among them is DOF, with the full, cyclic,

[6]Note as a special case that in the two-generation collector the (single) remembered set is always empty following a collection, thus the write barrier at collection time can be elided.

sweep of the heap. The directional filtering for the DOF scheme is shown in Figure 3.15 for pointer stores in the mutator.

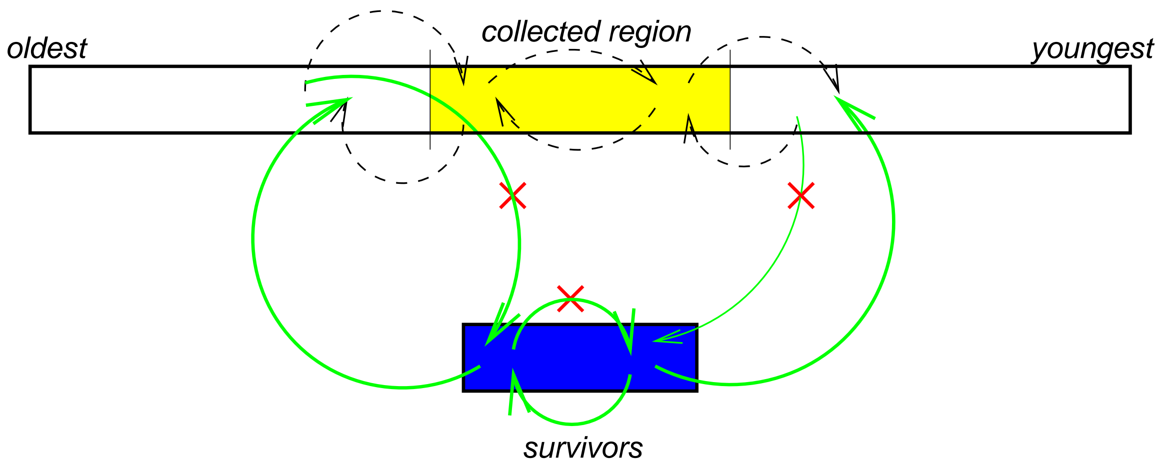

Figure 3.16. Directional filtering of pointer stores at collection time (DOF).

Distinguishing the region that will be collected next, and the regions older and younger than it, there are 12 cases of pointer stores at run-time. One half are eliminated by observing that the source will be collected before the target, and additionally, the case with both source and target within the region of the following collection is eliminated.

In Figure 3.16 we show the filtering scheme for pointer stores during collection. The dashed lines indicate the pointers as they existed before the collection, and the full lines indicate the pointers established during the collection, as survivor objects are copied into to-space. Here the filter eliminates 3 out of 6 cases. The actual benefits of directional filtering depend on the distribution of different pointer store directions, and we shall return to this question in Section 6.2.

In the design of remembered sets for the newly proposed collectors, there is an additional consideration that did not arise for generational collectors. Namely, when a collection copies objects from the collected set C into the survivors set S, then any pointers from C into the uncollected remainder U, recorded in the remembered sets of the blocks of U, must be discarded prior to collection. Otherwise, the remembered sets would contain entries for source addresses in the from-space of the collection, which, following the collection, are invalid. The

collection then reestablishes remembered set entries for the surviving pointers from S into U. Therefore, the data structure for remembered sets must support deletion efficiently. (In generational collection, the pointers from C to U are younger-to-older, hence they are not recorded in remembered sets to begin with.)

3.2.3 Write barrier

We now consider how to construct remembered sets. In between collections, new pointers come into being by means of initialization of pointer-typed fields of newly allocated objects, and by updates of these fields in older objects. Pointer updates are tracked using a write-barrier mechanism. As for pointer initialization, either the initializing stores are tracked using the same write-barrier mechanism, as it is, in effect, done in the Smalltalk system, or the newly allocated area is scanned for pointers at garbage collection time.

We consider two write-barrier mechanisms. The first write-barrier mechanism immediately inserts stores into remembered sets. When a store occurs in the mutator, the following filtering actions occur. First, it is established that the store is of a pointer as opposed to a non-pointer value. In dynamically typed languages such as Smalltalk, this check is at run-time. In statically typed languages, such as Java and Modula-3, the write barrier code is only emitted for pointer stores, so this check disappears. Second, the write barrier verifies that the stored pointer value (the target) is not nil, since such stores do not create new pointers. Third, the write barrier verifies that the pointer crosses block boundaries. This check involves the comparison for equality of the high-order bits (full address length less b) of the pointer source and target. Fourth, if the particular age-based scheme permits further elimination of pointers according to the age of the source and target, then the write barrier may eliminate some additional stores. Fifth and last, the pointer source is inserted into the remembered set of the block corresponding to the target.

The second write-barrier mechanism is a hybrid of *card marking* and remembered sets [Hosking and Hudson, 1993]. The heap is logically divided into cards of size 2^c bytes, where

$c \leqslant b$. Experience with generational collectors suggests that cards are typically much smaller than blocks: e.g., while blocks of 64 KB were used in a Smalltalk implementation, the most efficient card sizes were in the range 256 bytes – 1 KB [Hosking *et al.*, 1992; Hosking and Hudson, 1993]. A card table is an array with an entry for each card of the heap. At the end of a collection, all entries of the card table are *clean*. In between collections, at every pointer update (the store of a pointer $p \to q$) the write barrier marks the entry for the card containing p as *dirty*. At the beginning of each collection, the collector scans the card table to find dirtied cards. For each dirtied card table entry, it then scans the corresponding card in memory, i.e., it examines all pointer-valued fields in all the objects in the card, and updates appropriate remembered sets—in our example, it is the remembered set of the block containing the address q. When cards are examined and summarized into remembered sets, the same filtering criteria apply as discussed above for the case of immediate insertion into remembered sets. One benefit of card marking is that *duplicate* entries are immediately eliminated. The price is paid instead in scanning the cards, since the location of the updated pointer source is recorded only imprecisely. (When scanning a card, the collector may examine many more pointers, depending on the size of the card, in addition to the one (or ones) that caused the card table entry to be dirtied.) We shall see, however, that there are few duplicates *within* a block (Section 6.1.3), thus card marking is not likely to be profitable.

3.2.4 A write barrier design for large address spaces

Returning to the write-barrier mechanism without card marking, we observe that it can be implemented especially efficiently if a large virtual address space is available. The goal is to make the sequence of write-barrier instructions short for the common case, namely that of stores that the barrier does *not* record. A large address space allows a heap organization that avoids the need to index into a block table and is able to make the pointer update filtering decisions solely from the two addresses of pointer source and target, which are already available in hardware registers for the store itself.

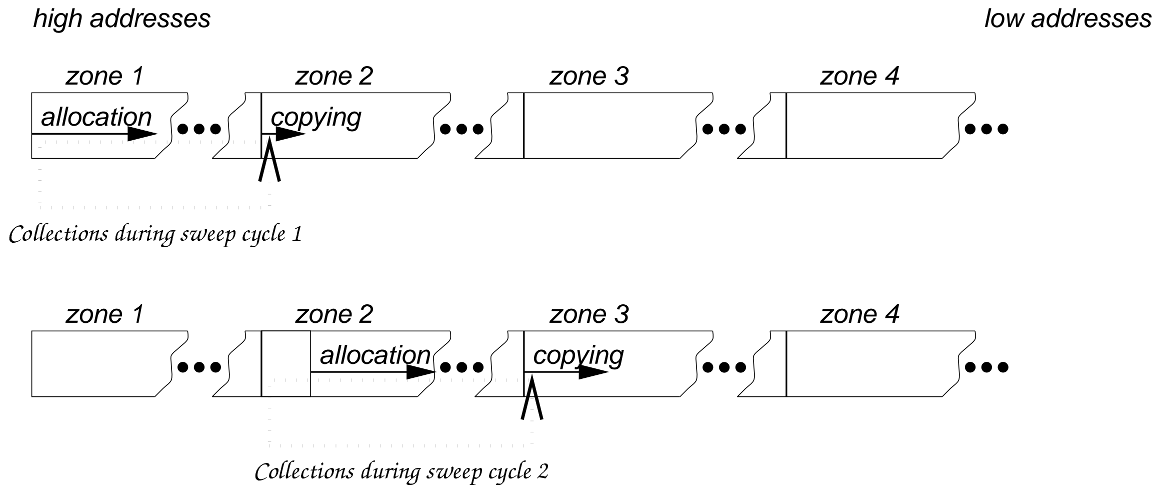

Figure 3.17. DOF heap organization in a large address space.

We illustrate the heap organization in Figure 3.17.[7] The address space is divided into zones, each zone consisting of a large number of blocks. At any moment exactly two adjacent zones are in use for the heap. Initially, all allocation is into zone 1, at the high end of the address space, whereas all copying by the collector is into the next lower zone 2. Both allocation and copying proceed from higher to older addresses within a zone. As soon as the amount allocated in zone 1 becomes equal to the specified heap size (expressed as a number of blocks), garbage collection begins in the DOF manner, with the collection window sliding over zone 1, from high addresses to low. The survivors of collection are copied over into zone 2. Subsequent collections are triggered when the total amount in the heap (i.e., in zones 1 and 2) again equals the specified heap size. This process continues until either: (a) the window of collection catches up with allocation in zone 1, or (b) the allocation in zone 1 reaches the limit, i.e., runs into zone 2. Case (a) corresponds to the natural end of the window sweep of the DOF collector (Figure 3.9). Case (b) is coerced into case (a) by enlarging the window to encompass the entire remainder of zone 1. Thus in both cases a full sweep of all objects allocated in zone 1 is completed. At this point, which corresponds to the resetting of the window in Figure 3.9, zone

[7]Note that the address-ordered layout of Figure 3.17 is logically equivalent to the age-ordered layout of Figure 3.9.

1 is abandoned, and its role is assumed by zone 2: allocation proceeds in zone 2, from the last copied object on towards lower addresses. Zone 3 is introduced for the survivors of subsequent collections.[8] In this fashion, allocation and collection can proceed until all zones have been exhausted. Under the assumption that we have a large virtual address space, most programs will not exhaust all available zones; if that does occur, however, the remedy is to move the data back into the high addresses, at the price of one non-generational collection (or relocation).

Choosing a good size for the zones is challenging. On the one hand, a zone should accommodate the amount allocated during one sweep of the collection window: if it does not, then the premature end of sweep will be forced (case (b) above), which will result in a longer-than-normal pause time and disturb the desirable operation regime of the DOF collector. On the other hand, when the DOF collector is in its most desirable regime, Figure 3.10, then the window moves slowly, and the amount allocated during a sweep is large. Therefore, since both the number of zones, and the size of a zone must be large, a large virtual address space is truly necessary for this organization to be effective.

The directional filtering at run-time, shown in the age-order layout in Figure 3.15, becomes very simple in this address layout, as shown in Figure 3.18: if the address of the pointer source is higher than the address of the target, the pointer store need not be recorded. Thus the directional filter can be implemented in a single comparison instruction. Note that the store of a null pointer, normally represented as a machine 0, is also caught by this filter, hence a separate prior check is not needed. The block-local filter remains as described above, but it can be coalesced with the directional check: one of the values compared in the directional check is first rounded to the nearest block boundary. In all, the filters require only a handful of instructions (a bit-masking operation, a comparison, and a conditional branch) and involve no memory accesses (Figure 3.20, p. 48, on the left).

---

[8] The operating system must cooperate by allowing the garbage collector to acquire and explicitly dispose of segments of the address space.

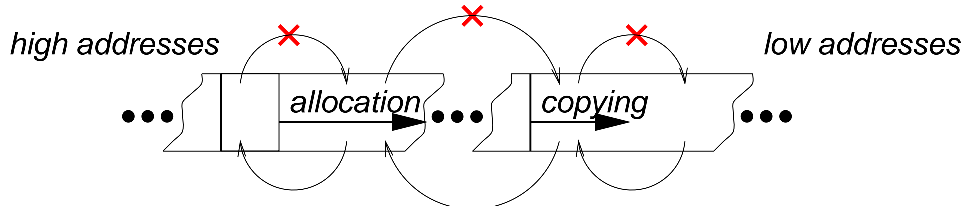

Figure 3.18. Directional filtering for DOF in a large address space.

Thus, the majority of pointer stores, those that do not need to be recorded, are handled quickly. We now consider the remainder. We have observed (as we report in Section 6.1.3) that there are very few duplicate pointer stores for the remembered set of a block in general, and, in particular, between two collections. Hence card marking is not advisable. However, if we wish to keep the cost of the write barrier predictable and low, we should not immediately insert the pointer store, that is, the address of the pointer source, into the remembered set of the pointer target. Instead we can write the same address into a sequential store buffer [Hudson *et al.*, 1991], and subsequently flush the store buffer into the remembered set. There will be a sequential store buffer for each block in current use.

At collection time, we form the set of remembered pointers into the collected region by considering the "union" of the remembered sets of all blocks in the region. We chose to maintain the remembered set of a block between collections as a sequential store buffer; now, rather than construct the remember set explicitly and then compute the union, we simply merge the store lists for the blocks involved, and eliminate pointers that go between two blocks both in the collected region.[9]

Recall that when remembered sets are explicitly maintained, it is necessary to purge the sets of uncollected blocks of entries for pointers from collected blocks, prior to collection. With the address layout proposed here, together with directional filtering, that is no longer necessary,

[9]Note that each store buffer is likely to be a nearly sorted list (with decreasing addresses), because most pointer stores are into the newly allocated area, and thus the sequence of pointer source addresses is correlated with the direction of allocation. This circumstance may influence the choice of the merge algorithm. Also note that an actual merge operation is not absolutely required: it is possible, and it may be less expensive, to recognize duplicate entries on the fly.

since entries cannot become stale: the collected region lies within the highest valid addresses, and no pointers from higher, now invalid addresses, were recorded in the remembered sets for the collected region, since such pointers would have been higher-to-lower address pointers.

The directional filtering described here is cheaper than the traditional generational test [Hosking *et al.*, 1992], which requires indexing into a block table to determine the generations of the pointer source block and the pointer target block, at the cost of two memory accesses. For fairness, however, under the assumption of a large address space, the generational test can also be simplified. We divide the address space into a number of very large blocks, and assign each generation to one block. We place the nursery at the highest addresses, and older generations at progressively lower addresses. With this heap layout, an address comparison acts as a generational test to eliminate younger-to-older stores, and simultaneously handles the null pointer store; a block-local filter is needed to eliminate older-to-younger stores within a generation.

Thus the write barrier cost components—the cost incurred for each pointer store and the additional cost incurred for each pointer store that must be recorded—will be comparable in implementations of the collectors studied. Similarly, the costs incurred at the time of processing each remembered set entry will be comparable. Therefore, in this study we focus on measuring the number of times different collectors invoke each of these operations. We find significant differences between the collectors. Chapter 6 describes these results in detail.

3.2.5 An estimation of copying and pointer-maintenance costs

In subsequent chapters we shall obtain accurate operation counts for the copying and pointer-maintenance actions of garbage collection. If in addition to the number of operations, we know the cost of each operation, we can calculate total collection costs, and by comparing with an actual implementation, validate the cost model.

We performed preliminary experiments with the proposed write barrier on a 292 MHz Alpha 21164 processor. The implementation is presented in Figure 3.19 as source code and in

Figure 3.20 as Alpha assembly code compiled using `gcc -O2`. The null-pointer, block-local, and directional filtering are accomplished using a single test. The estimated overhead of the barrier if the test eliminates the store is 2 cycles.[10] Stores that are not eliminated are recorded, without duplicate removal, in a sequential store list corresponding to the target block. A sequential store list holds a maximum of 15 entries. When a store list fills up, a new one is allocated from a large linear arena; thus each block owns a linked list of sequential store lists. The measured overhead of the barrier, including the writing into a sequential store list and management of sequential store lists, is 11 cycles per store.

Figures 3.21 and 3.22 present the code executed at garbage collection time to scan the list of sequential store lists of a block. The collector retrieves each entry, interprets it as a pointer source, and then reads the current target value of this pointer. (The target may have changed since the time when this store was recorded, so the collector verifies that the current target is within the collected region.) Finally, the collector retrieves the header word of the target object. If the header word is in fact a forwarding pointer, then the object need not, and must not, be copied again. If the header word is a true header, then this is the first time the collector has encountered the object in this collection, and therefore the collector copies the object into to-space. (A forwarding pointer is an object address and its least significant bit is 0, because objects are word-aligned, while addresses are expressed in bytes. We can define a true header to have 1 in its least significant bit to make headers and forwarding pointers distinguishable.) The cost of this entire sequence, sans copying, is 13 cycles per processed entry.

Thus, assuming that filtering succeeds in eliminating 95% of pointer stores on average, and assuming that all recorded stores are eventually processed, the average cost per pointer store is estimated at $0.95 \cdot 2 + 0.05 \cdot (11 + 13) = 3.1$ cycles.

---

[10] The measured overhead on the four-way issue Alpha 21164 processor ranges from 1 to 3 cycles for the three instructions in the test, depending on the surrounding code; the average and median of 2 is used in the absence of any assumptions about the surrounding mutator code.

In addition to the break-down of pointer-maintenance costs, we performed an experiment to measure the components of copying cost in detail. Whereas in the aggregate, the copying cost is roughly proportional to the amount copied, here we examine the contribution of individual operations to that cost. Our model assumes a copying collector, in which a first phase of root processing (processing of global roots and remembered sets) is followed by a Cheney scan of to-space. For each object copied, the collector pays the following three costs: the cost of processing the pointer that keeps the object reachable, the overhead of installing a forwarding pointer and preparation for copying the words of the object, and the overhead of preparation for scanning the pointer fields of the object. Together these three are the per-object cost α_{obj}. For each word copied, there is a cost α_{word}. Finally, in the scanning phase there is an additional cost for each scanned pointer that does not cause an object to be copied (whereas scanning a pointer that does cause an object to be copied is subsumed in α_{obj}). There are three circumstances when this happens: the pointer is null; the pointer points outside the collected region; or the pointer points to an object that has already been copied. In our large address space model, these three circumstances are identified as follows: category *null/lower* encompasses null pointers and pointers to addresses below the collected region (addresses above the collected region are not possible at collection time), and category *duplicate* encompasses pointers into the collected region to objects that have already been copied. The per-pointer-field costs for these two categories are $\alpha_{null/lower}$ and $\alpha_{duplicate}$, respectively. The full copying cost is then

$$c = \alpha_{obj} n_{obj} + \alpha_{word} n_{word} + \alpha_{null/lower} n_{null/lower} + \alpha_{duplicate} n_{duplicate}.$$

We measured the operation costs α in a synthetic copying experiment, in which heaps of different size, and with different object sizes and pointer contents were constructed and copied by a collector. We used an object format applicable to a typed language such as Java: an object header word points to a class record, which points to class-specialized methods to copy and scan the objects. We estimate the following values for the operation costs on the Alpha 21164, for operation within the primary cache: $\alpha_{obj} = 65$ cycles, $\alpha_{word} = 2.5$ cycles,

$\alpha_{null/lower} = 15$ cycles, and $\alpha_{duplicate} = 17$ cycles. These estimates could be used in conjunction with an instrumented garbage collector to validate the detailed model of copying cost.

One must be cautious with these numbers for processor cycles spent on particular operations. They were obtained in a tight loop, and may not reflect actual costs accurately. On the one hand, the cost of memory accesses is discounted, since block table entries are cache-resident. On the other hand, cycle counts may be overestimated, since the processor has no opportunity to interleave the write barrier instructions with other mutator instructions.

3.3 Summary

The proposed class of age-based collectors represents a logical generalization of the concept of generational collection. Age is the simplest criterion for choosing the collection region, and there are established techniques for encoding object age with sufficient accuracy and reasonable overhead; we have also suggested new techniques applicable to large address spaces that promise to reduce overheads further even in the more complex context of age-based collection.

The collectors as described are all of the stop-the-world variety. No explicit provisions for incrementality are suggested. However, we believe that collectors with a small fixed size collected region can provide sufficiently low maximum pause times that they can be considered truly incremental (even if they have to do so at the price of increased total time).

We described the collectors as operating within a unified heap, in which all objects lie. Hence, the same basic policy is applied to newly allocated objects as to older objects, and even long-lived semi-permanent objects. Surely the motivation that has led researchers in the past to consider dividing the heap into ephemeral and mature spaces remains valid, and different age-based schemes could be applied within each division.

We described simple oldest-first, youngest-first, and moving window schemes (Figure 3.23 summarizes the employed abbreviations). The space of other possible designs is vast, and

CHAPTER 4

EVALUATION: SETTING

The evaluation of garbage-collection algorithms requires us to pose a large number of questions in order to expose the strengths and weaknesses of algorithms in different circumstances. We developed a number of different experimental methods to answer them and we present these methods in detail here and in the following two chapters: the discussion of each method is immediately followed by a presentation of the experimental results.

The three main approaches to a comparative performance evaluation of garbage collector performance, offering different perspectives, are analytical modelling, trace-based simulation, and prototype implementation. *Analytical modelling* consists of constructing a mathematical description of the operation of the garbage collection algorithm, and applying it to a mathematical description of the load, i.e., the allocation and lifetime properties of objects and pointers. When successful, analytical modelling provides succinct models, and has useful predictive power with respect to the choice of collector configuration. Unfortunately, the premise of having reliable realistic mathematical descriptions of lifetime properties of objects, and especially properties of pointers, is not easily met with current knowledge.

Trace-based simulation consists of constructing a software simulation of the operation of the garbage collection algorithm, and applying it to an empirically obtained trace of the load, i.e., the sequence of allocations and other object-related operations of a real program. Simulation isolates the memory management tasks from other (computational) tasks that a real program performs, and allows a variety of configurations to be tried. It is even possible to try collection algorithms that would be excluded in practice, such as those using backtracking, or oracles, in their decisions. The analysis of simulation results provides explanatory and predic-

tive power, but is not as succinct as analytical modelling. It is usually not difficult to extract traces when a working garbage collector is given, thus one can reasonably obtain traces from more than one object system and analyze them within the same simulation framework.

Prototype implementation consists of constructing complete garbage collection algorithms and implanting them in a working object-based system, in order to measure how each performs in operation. Implementation has the advantage that it accounts for the full cost of memory management; on the other hand, it is difficult to extract the contribution of each cost factor. Furthermore, that cost is necessarily a reflection of a number of implementation decisions. From a practical standpoint, it is a usually a difficult task to retrofit (a number of) garbage collectors onto a working system.

Our study primarily uses trace-based simulation using specially built object-level simulators. A prototype implementation was also completed according to the design of Section 3.2, and integrated with a trace simulator, which allows us to gather many of the performance statistics as in a working object system.

In the remainder of this chapter, we discuss our experimental setting: the design of the garbage collection simulators and the set of benchmark programs used. The following two chapters present the findings: Chapter 5 examines the copying cost of collection, and Chapter 6 examines non-copying costs of collection, viz., the cost of collector invocation, and the pointer management costs.

4.1 Evaluation using program traces

The primary method used in this study is evaluation by trace-based simulation. The experiment proceeds in two phases. First, by instrumenting an object-based system and executing a program, a trace is produced. Second, the trace is used to direct the execution of different garbage collection algorithms and to derive statistical measures of the program.

4.1.1 Trace content

The information contained in the trace must permit accurate simulation of each garbage collection algorithm. To the point, the trace must identify all objects that the program allocated in the heap, providing for each object its time of allocation, its time of demise, and its size.[1] Furthermore, all stores of pointer values into the objects in the heap must be present in the trace.

This information is sufficient for a garbage collector simulator to determine which objects are reachable in any chosen collection area at any chosen time. A real collector first identifies global roots by scanning the stack, and then computes the transitive closure of the points-to relation to find the reachable, hence live, objects. As it will be described below, the simulated collector relies instead on accurate allocation and demise records: all objects for which an allocation record has been seen but not a demise record, are live. In addition, the trace allows the collector to maintain an accurate image of the pointers among heap objects. In particular, the pointers from the uncollected region into the collected region are accurately known. Thus the closure of the points-to relation can be computed in the simulator to complete the set of collection survivors.

4.1.2 Trace format

The common format for the traces is as follows. Each trace is a text file, in which each line records an event. Three kinds of events are represented: object allocation (A-records), object demise (D-records), and field update (U-records). An allocation record has the form:

`A` *allocation-address* *size*

where *allocation-address* is the hexadecimal byte-address of the starting word of the object, and size is the number of words in the object. A demise record has the form:

[1]These are the properties meaningful in *every* object-based system. In some systems it may be worthwhile to report more detailed information, when it is defined in the language at hand, such as the type (or class) of the object, or the allocation point. However, since age-based garbage collection algorithms do not make use of such information, we shall assume that only the general properties, applicable to all object-based systems, are recorded.

`D` *allocation-address*

where *allocation-address* is the hexadecimal byte-address of the starting word of the object. An update record has the form:

`U` *field-address* *value-address*

where *field-address* is the hexadecimal byte-address of the field which is being updated, and *value-address* is the pointer value stored. (The special value -1 represents the store of a *null pointer*.) The form of the traces reflects the assumption that an object is a contiguous sequence of fields, each field being an integer number of words. A pointer-valued field takes one word. A word is the smallest quantum of allocated space, and therefore all sizes and amounts are reported in words. In the systems studied (Smalltalk and Java 32-bit implementations), a word is four bytes long. Another assumption implicit in the trace format is that the location of an object is immutable. This assumption was made for simplicity: rather than have a separate notion of object identity, the address (whether allocation address or a field address within the object) uniquely identifies the object. Without loss of generality, it may also be specified that allocation addresses of objects in the trace follow consecutively, as if the objects were allocated from an infinite allocation area starting at zero.

4.1.3 Trace generation

Having described the content of the trace, let us consider how to generate a trace. For this study, the method is to augment an existing object-based system and its garbage collector with code to produce the required trace records. The existing system is assumed to have the functionality to identify each object allocation, object demise, and pointer store.

Every object-based system can identify object allocations.

Every system with a garbage collector can also identify object demise. However, if we rely on the garbage collector existing in the system (often a state-of-the-art generational collector), we must ensure that the collections consider the entire heap, as in a non-generational collector,

to avoid the inaccuracies of excess retention (Section 5.3).[2] Following each such full collection, the reachability of objects is accurately known; any objects that are now not reachable, but were reachable at the previous full collection have died in the intervening period. If the time of demise must be known with accuracy, the period between full collections must be short. In fact, it is critical for the correctness of *simulated* collections to be able to determine reachability at every possible garbage collection instant (in simulation), i.e., *following every object allocation* (in simulation). Therefore, a full collection (in trace generation) must also follow every object allocation. As a result, the trace generation mechanism is very expensive: full collections are expensive, and many are needed. In fact, the cost is roughly proportional to the integral $\int_0^T v(t)dt$ of the live data amount over the duration of the program.[3]

Update records, the final component of the trace, are easily generated by instrumenting the write barrier in a system with a generational collector, since the collector must be informed of pointer stores. One must only ensure that in the existing system the write barrier is indeed invoked for each pointer store, that is, the system does not optimize away some pointer stores (e.g., initializing stores or null pointer stores), which it is allowed to do for operation of a generational collector, but not for trace generation.

Let us consider some questions about traces generated in this manner. Any measurement disturbs the system measured, and generating object traces is no exception. If the traced program relies on timing properties, such as by querying a real-time clock, its behavior will be severely disturbed by the heavy overhead of tracing. We do not have such programs among our benchmarks. If an application is multi-threaded, as many interactive Java programs are, and

[2] It is additionally assumed throughout that the collector is accurate (as opposed to conservative). It is certainly possible to obtain traces with a conservative collector, such as the one found in the Kaffe virtual machine for Java, but the utility of such imprecise traces is dubious: the garbage collection schemes in this study are meant to be accurate, not conservative.

[3] Note that the underlying assumption is that the existing object-based system and its garbage collector are to be exploited with minimally intrusive modifications—as dictated by technical considerations when dealing with large and complex systems, and also dictated by legal and commercial considerations when systems are not available for inspection and modification in their entirety. If, on the other hand, a system can be redesigned for the express purpose of generating our traces, then better solutions are possible than repeated full collections, in the form of incremental computation of object reachability.

if garbage collection requires synchronization of all threads, then the concurrency behavior of the application will be changed under tracing. The observed order of execution will be a valid order, but not a likely, or the "intended" order.

Finally, recall that in the common trace format the object addresses are immutable. If the tracing object-based system uses moving collection, it is necessary, but easy, to translate object addresses into the absolute form.

4.2 Benchmarks and languages

We first consider the object-based systems ("languages") used in the study, and then the benchmark programs, detailing their general properties.

4.2.1 Languages

We used two object-based systems. The first, **Smalltalk**, is an older purely object-oriented language [Goldberg and Robson, 1983], which consists of three parts: the virtual machine, implemented in an earlier effort in the Object Systems Laboratory [Moss, 1987; Hudson *et al.*, 1991; Hosking *et al.*, 1992], the basic virtual image of Smalltalk-80 from PARC Place/Digitalk, and the additional classes and methods of the benchmark programs. The virtual machine includes the language-independent garbage collector toolkit, also developed in the Object Systems Laboratory [Hudson *et al.*, 1991]. The virtual machine provides the execution (by interpretation) of the bytecodes in the methods contained in the basic virtual image and the benchmark classes.

In the Smalltalk system, all of these classes and methods are present as objects in a benchmark virtual image, which is loaded at program start-up to build an initial heap state. When generating the trace, we distinguish between these objects and objects subsequently allocated as a result of program execution. The main results reported here reflect the program execution objects alone. This choice is justified by the observation that image objects could better be treated as static, instead of as part of the garbage-collected heap [Clinger and Hansen, 1997].

Another property of this implementation of Smalltalk is that method activation records (frames) are internally treated somewhat like objects [Moss, 1987]. However, frames are not treated as objects for the purposes of trace generation.

The second system used, **Java**,[4] is a contemporary object-oriented language that has found much use in Internet-based downloadable applications. It consists of a virtual machine, and a set of basic and benchmark classes and methods, loaded on demand. The Java virtual machine modified to generate traces for this study is an experimental machine, called the ExactVM, developed by Sun Microsystems Laboratories, which is equipped with a garbage collector that satisfies all the requirements outlined above. The Java virtual machine used has the option of running as interpreter, or as a just-in-time compiler. The same objects are allocated, and in the same order, in either case, and pointer updates, and, consequently, object demise points, also happen in the same order—as long as the compilation does not interleave the compiled code from successive bytecodes. Since any differences in behavior, if at all present, are incidental and not material to this study, they can be ignored. The interpreted mode of operation was then chosen for reasons of simplicity.[5]

4.2.2 Benchmarks

The selection of benchmark programs for evaluating garbage collector performance is not an easy task. There is no widely-accepted suite of benchmarks, unlike for general computer performance evaluation, where there are several (e.g., SPEC95). It was therefore necessary to collect and select useful benchmarks from various sources, and it was also necessary to develop the selection criteria.

---

[4] Java is a trademark of Sun Microsystems.

[5] To generate traces using the just-in-time compilation mode, it is necessary to modify the code-generation phase of the compiler so that it will produce appropriate code at object allocations and at pointer stores. Our experience with the Kaffe virtual machines shows this to be a relatively straightforward exercise if the compiler is cleanly written. It is, however, a futile exercise, because the performance advantage of compiled code is entirely annulled by the overhead of trace generation.

4.2.2.1 Collecting benchmarks

Collecting a large preliminary set of benchmarks posed distinct challenges in both languages under consideration. For Smalltalk, although the language is no longer in vogue, a number of public-domain programs (i.e., classes) implementing interesting applications exist and can be obtained on the Internet. Unfortunately, many of these programs depend on the presence of some vendor-specific classes, or are otherwise incompatible with the virtual image used in our Smalltalk-80 system. To the programs we could find, we added some that we have written ourselves and used previously in a study of Smalltalk garbage collection performance [Hosking *et al.*, 1992]. We also translated two SPECfp95 programs from FORTRAN into Smalltalk.

That version incompatibilities should be encountered in Smalltalk, a language which in its present form dates back eighteen years, is perhaps not surprising. However, we found that significant incompatibilities exist even in Java, a much younger language. They are primarily caused by changes in the class library between versions 1.0 and 1.1, assumed by most applications, and version 1.2, which the tracing Java virtual machine uses. A more significant difficulty in collecting Java benchmarks is the fact that the vast majority of publicly available Java code is in the form of Java *applets*, partial programs which execute under the control of a Web-browser and depend on it for the user interface. A browser must contain a Java virtual machine, but that machine is not accessible for instrumentation. We can only use full-fledged Java applications, which run directly on a virtual machine. It is perhaps not a great loss, since the majority of observed applets appear to be graphical widgets and similar toy programs, which neither run long nor allocate much data. On the other hand, the resulting benchmark set is skewed in favor of language-processing tools (compilers and optimizers). Additionally, we had access to the traces (although not the sources) of a preliminary set of Java programs considered for inclusion in the SPEC JVM98 suite.

4.2.2.2 Selecting benchmarks

Having collected a larger set of programs (circa 30 Smalltalk and 15 Java) we considered which objective criteria should decide their utility as benchmarks of garbage collector performance. The first criterion must be that the program exercises the memory management functions at all. For instance, some Java graphics applications are CPU-intensive, but allocate a negligible amount of data, and are of no use in this study.

Even programs that do allocate an appreciable amount of data do not necessarily exercise the garbage collector. Many programs, in particular most of the SPEC JVM98 programs, display a monotone-increasing heap profile: they slowly allocate pieces of some large data structure from start of execution to the end. Since the heap must be at least as large as the maximum amount of live data ever in it (in our cost model and simulation, the heap size is fixed), the program never fills the heap and the garbage collector never runs. Thus, loosely speaking, we need the criterion that the garbage collector runs at all.

In fact, we need a stronger criterion. Consider that, over the execution of the program, the garbage collector will run at different moments depending on the garbage collection algorithm. The amount actually live depends, somewhat unpredictably, upon the precise moment of collection. (Perhaps the most obvious effect is at the end of program execution—since no copying cost is charged past the last collection.) It is thus necessary to reduce the "random" variation in measured collection performance that the "random" collection moments introduce, so as to expose underlying trends. It is therefore desirable to have a large number of collections to even out the "randomness"; in other words, it is desirable to have benchmarks that allocate a very large amount of data relative to their average *live* amount.

We can formalize this requirement by observing that the number of collections performed by a non-generational collector is approximately proportional to the ratio of the amount allocated to the average live amount (see below). We require this number to be more than 10 to admit a measurement. Furthermore, we admit a benchmark only if admissible measurement of non-generational collection is possible for a heap size three times larger than minimum. Thus,

if a benchmark is admitted, the range of admissible heap sizes is at least 1:2, non-generational collector requires more than 10 collections, and our investigated schemes typically require hundreds of collections, so the aforementioned "randomness" is largely avoided.

4.2.2.3 The final benchmark set

Our selection process resulted in a set of 11 Smalltalk benchmarks and 3 Java benchmarks. Their basic properties are listed in Table 4.1. Execution time was measured in normal operation, without any instrumentation and with default generational garbage collector configurations, on a 50 MHz SPARCstation 20 workstation. The amount of data allocated by the program is expressed in words (each word being 4 bytes). The remaining columns give the number of objects allocated, the maximum live amount in words (which is also the minimum required heap size to execute the program), and the number of pointer stores.

The results of non-generational collection for these programs are reported in Figures 4.1–4.10, pp. 71–80 (at the end of this chapter).

Let us take as an example Figure 4.5. In the graph in Figure 4.5(a), we have plotted the absolute mark/cons ratio $\mu_{\text{non-generational}}$ against total heap size V. It is easy to check that the shape of the μ curve closely fits the theoretical prediction, $\mu_{\text{non-generational}} = \frac{1}{\frac{V}{v}-1}$ [Appel, 1987; Jones and Lins, 1996], where v is the effective live data amount. In the graph in Figure 4.5(b), we have plotted the number of garbage collections n against total heap size V. The horizontal dotted line is drawn at $n = 10$, thus the region below the horizontal dotted line (and to the right of the dotted vertical) is the region of heap sizes so large that they result in 10 or fewer non-generational collections. Because of inaccuracies that may be introduced under such conditions, we do not compare results for this region.

We now describe individual benchmarks, providing where possible details of their structure.

Table 4.1. Properties of benchmarks used

Benchmark	Ex. time (s)	Words alloc.	Objects alloc.	Max. live	Ptr. stores
Smalltalk					
Interactive-AllCallsOn	1.91	18 359	1 722	627	855
Interactive-TextEditing	2.30	22 747	3 556	1 098	3 509
StandardNonInteractive	6.11	204 954	46 157	1 160	7 251
HeapSim	67625	3 791 306	1 084 650	93 026	30 298
Lambda-Fact5	6.88	277 940	53 580	6 295	91 877
Lambda-Fact6	55.86	1 216 247	241 864	13 675	404 670
Swim	11.65	1 533 642	444 908	17 542	134 355
Tomcatv	3.92	2 117 849	624 612	30 593	286 032
Tree-Replace-Binary	3.32	209 600	35 785	9 784	39 642
Tree-Replace-Random	4.55	925 236	189 549	13 114	168 513
Richards	10819	4 400 543	652 954	1 498	763 626
Java					
JavaBYTEmark	353.76	1 161 949	109 896	59 728	49 061
Bloat-Bloat	387.54	37 364 458	3 429 007	202 435	4 927 497
Toba	178.05	38 897 724	4 168 057	290 276	3 027 982

- Interactive-AllCallsOn and Interactive-TextEditing. Two tests from the standard sequence specified in the Smalltalk-80 image [Goldberg and Robson, 1983], comprising only the macro-tests. Previously used in Ref. [Hosking *et al.*, 1992].

- StandardNonInteractive. A subset of the standard sequence of tests as specified in the Smalltalk-80 image [Goldberg and Robson, 1983], comprising the tests of basic functionality.

- HeapSim. Program to simulate the behavior of a garbage-collected heap, not unlike the simplest of the tools used in this study. It is however instructed to simulate a heap in which object lifetimes follow a synthetic (exponential) distribution, and consequently the objects of the simulator itself exhibit highly synthetic behavior.

- Lambda-Fact5 and Lambda-Fact6. An untyped lambda-calculus interpreter, evaluating the expressions 5! and 6! in the standard Church numerals encoding [Barendregt, 1984, p.140]. Previously used in Ref. [Hosking *et al.*, 1992]. Both input sizes are used in order to explore the effects of scale.

- Swim. The SPEC95 benchmark `102.swim`, translated into Smalltalk by the author: shallow water model with a square grid.

- Tomcatv. The SPEC95 benchmark `101.tomcatv`, translated into Smalltalk by the author: a mesh-generation program.

- Tree-Replace-Binary. A synthetic program that builds a large binary tree, then repeatedly replaces randomly chosen subtrees at fixed height with newly built subtrees. (This benchmark was named Destroy in Ref. [Hosking *et al.*, 1992; Hosking and Hudson, 1993].) Tree-Replace-Random is a variant which replaces subtrees at randomly chosen heights.

- Richards. The well-known operating-system event-driven simulation benchmark. Previously used in Ref. [Hosking *et al.*, 1992].

Our set of Java programs is as follows:

- JavaBYTEmark. A port of the BYTEmark benchmarks to Java, from the BYTE Magazine Web-site.

- Bloat-Bloat. The program Bloat, version 0.6, [Nystrom, 1998] manipulating the class files from its own distribution.

- Toba. The Java-bytecode-to-C translator Toba working on Pizza [Odersky and Wadler, 1997] class files [Proebsting *et al.*, 1998].

4.2.3 Properties of benchmarks

We now examine some properties of the benchmark programs. We have already seen their behavior under non-generational collection. Before we proceed to their behavior under different age-based collectors, we look at those properties that are *independent* of any collection algorithm. We examine the distribution of object sizes, the distribution of object lifetimes, and the time-varying live amount profile. We shall later refer to these properties when we look for

causes of particular performance behavior, but we shall find that their predictive value is not as great as expected.

We first look at the distribution of object sizes: the typical sizes of objects, and how much sizes deviate from the typical. The size of a *block* must be substantially larger than the typical object size in order to avoid fragmentation. More to the point, the fraction of objects larger than the block size must be small, to minimize the overhead of allocating in the Large Object Space, and the overhead of subsequent collections of objects in Large Object Space [Hicks *et al.*, 1998]. The distribution we measure is a time-averaged property: we do not consider how the numbers of small and large object in the heap change over time.

The size distributions for our set of benchmarks are presented in Figures 4.15– 4.28 (pp. 85–98). The distributions are computed according to four different weighting criteria: (a) by count of objects alone; (b) by volume, which is the object size itself (to reflect the fraction of the heap occupied by objects of a particular size); (c) by lifetime (to take into account that a longer-lived object is more likely to be encountered in collection); and (d) by both volume and lifetime. Each row of a figure corresponds to a weighting criterion. The left column gives the distribution in raw form, as a histogram, whereas the right column gives the cumulative distribution, normalized to 1, so that fractions can be read off easily.

Most programs have several dominant object sizes that constitute most of their allocated volume. Weighting is important: whereas, for instance, 99.5% of allocated objects in Swim are 10 words or smaller, these objects account for 95% weighted by volume, 92.5% weighted by lifetime, and just 50% weighted by both volume and lifetime (Figure 4.21, p. 91). The latter is the most realistic measure of the distribution as seen by a garbage collector,[6] and as we see, if small objects have short lifetimes, their participation in the load can be much less significant than their *numbers* may suggest. We note similar behavior—that smaller objects

[6]We note that age-based collectors that examine less than the whole heap are able to bias the distribution of the objects they see in particular ways with respect to the lifetime, though not with respect to size. Other (non-age-based) collectors are free to *use* size in their allocation decisions.

have shorter lifetimes than larger objects—in all Smalltalk and Java programs except three. The three exceptions are HeapSim, Lambda-Fact5, and Lambda-Fact6, in which a single size represents such an overwhelming fraction of allocation that no differentials can be observed, hence the cumulative distribution curves for different weightings are indistinguishable.[7]

As we have noted, many arguments about garbage collection performance invoke the properties of object lifetime distributions [Baker, 1993; Clinger and Hansen, 1997], sometimes assuming *a priori* distributions in order to derive tractable mathematical models. Even though it is not our goal to develop analytical models, it is proper to evaluate our benchmark set with respect to object lifetime distributions. We shall see that the relationship of the distribution to actual performance is tenuous.

We present the lifetime distributions by means of the survivor function and the mortality function (Section 2.2), shown for our benchmark set in Figures 4.29– 4.42 (pp. 99–103). For each benchmark, the lifetimes of all allocated objects were taken together, weighted by volume (i.e., by object size) and a cumulative distribution was found. Thus, the lifetime distribution is another time-averaged property. Each figure (a) shows the survivor function, plotting object age on a logarithmic scale to show the interesting behavior at young ages more clearly. Each figure (b) shows the mortality function, obtained by numerical differentiation and suitable smoothing from the survivor function. Because of the inherent error of this numerical process, applied to data that are not intrinsically smooth, the mortality curves should be taken *cum grano salis*, as merely indicative of the lifetimes.

The fact that the survivor function is rapidly decreasing, even with a logarithmic scale for the age axis, confirms the observation made many times in the literature, that object lifetimes

---

[7]The most striking observation is that Java programs have large maximum object sizes, whereas only one Smalltalk program, HeapSim, has objects larger than 140 words. We note that block size in implementation is restricted to be a power-of-two multiple of the virtual memory page size, and that page sizes are of the order 1000–2000 words (8 KB, or 2048 words for Sun Solaris 2.5.1 running on an UltraSparc). Therefore, there is no additional constraint upon block size to make a large object space *unnecessary for these Smalltalk program executions*. The same program may allocate larger objects on a different input. Whether the potential reduction in memory management overhead, by not having a large object space, is significant, and worth the expense of compile-time analysis needed to prove that no large objects are allocated, is beyond the scope of this work.

tend to be short. A few programs exhibit significant fractions of allocated data living to ages close to the duration of the program (Swim, Tomcatv, HeapSim, Tree-Replace-*, Bloat-Bloat, Toba). In others, the survivor function approaches negligible values at an age two orders of magnitude below the duration of the program.

It is tempting to make performance predictions by extrapolating from lifetime distributions. We can speculate that the presence of sharp peaks in the mortality curve (as in StandardNon-Interactive, Figure 4.31, and Richards, Figure 4.39) indicates an opportunity for good performance of the FC-DOF collector, provided that the *age* of high mortality translates into a *heap region*, compatible with the collection window, with low copying cost. On the other hand, there is little to distinguish the survivor functions of Lambda-Fact5 (Figure 4.33) and Richards (Figure 4.39), yet we shall see that their behavior under age-based collection is radically different.

In addition to the preceding time-averaged properties, we look at the live profile: the amount of live data in the heap as a function of time. Our traces already express exact liveness information, thus it is easy to produce the live profiles, given in Figures 4.43– 4.56. The live profiles reveal periodic patterns, as in Figures 4.48 and 4.49, which result from iterative or recursive control structure of the program.

4.3 Simulating garbage collection

The primary goal of garbage collection algorithm simulation in this study is to estimate the copying cost of collection. The simulators accurately compute the amount of data copied in collection; this amount is a good estimate of copying cost. In addition, the simulators compute the number of objects copied, the number of garbage collections invoked, and other secondary statistics.

We first describe object-level simulators. They do not model the costs realistically incurred in remembered set maintenance, although they themselves do maintain per-object remembered sets. These costs will be addressed in Section 4.3.3 using block-level simulation based on the prototype implementation. The simulators do not model the locality effects, namely the lo-

cality of access within the collection process, the locality from one collection to another, the locality interference between the mutator and the collector, and lastly, instruction locality. The organization of the simulator is entirely different from that of a realistic garbage collector, thus any timings or locality measurements of the simulated collector are meaningless; moreover, the computational actions of the mutator are not available at all in the trace. These effects can be of interest on modern hardware, and they should be considered in future implementation experiments. However, the primary cost, which is that of copying, is accurately measured by simulation. Simulation has additional benefits, such as the freedom to explore configuration spaces thoroughly and at low cost since computation is eliminated and only memory management is simulated, the freedom to explore new collection algorithms *in abstracto*, and the ability to operate with a common trace format uniformly for various source languages.

The number of garbage collections invoked is easily and accurately obtained by simulation. It is of some importance in evaluating the performance of an algorithm. Each invocation of the collector entails a considerable overhead: the collector must find the global roots of the collection, typically by scanning the execution stack (or multiple stacks in multiple threads of computation). For this reason, the scheme with fewer collector invocations would be preferred, *ceteris paribus*. However, the number of invocations can be viewed from a different angle: the fewer collections there are, the more work is done by each, and the longer the pauses are. In an interactive or real-time setting especially, it is desirable to limit pause times. More precisely, a garbage collection algorithm that imposes an upper bound on the amount of work at each collection may be preferable, in spite of a larger number of collector invocations, to a collector that performs a smaller number of collections, each of longer duration.[8] In summary, it is not appropriate to use the number of garbage collections invoked as a performance measure without reference to the intended application.

---

[8]Traditional generational collection performs a larger number of collections than non-generational collection, and these collections are on average shorter. However, it *occasionally* collects the entire heap, and thus its upper bound on the amount copied in a collection is not better than with non-generational collection.

4.3.1 General simulation algorithm

The simulation algorithm resembles in its outline the operation of an actual garbage collector (Section 3.1), but differs in important details. We begin with an informal account.

Let us first consider the actions of the simulator while it is simulating the actions of the mutator given in the trace. The simulator sets up a certain, immutable, heap size and an initial allocation area size, and then begins to read the trace. For each `A` record, the allocation area decreases by the size of the allocated object, a running total of volume allocated increases by the same amount, and a data structure is created to represent the object. The simulator maintains a global set of data structures representing all objects present in the heap. A splay-tree data structure [Sleator and Tarjan, 1983] is used for the purpose, because of its good temporal-locality properties. For each `D` record, the simulator marks the corresponding data structure as *known-dead*, but does not discard it immediately. For each `U` record, the simulator first identifies the object in which the updated field is and the object to which the pointer points, and then it records the newly stored pointer in the data structures of the two objects. (The data structure for an object contains both the outgoing pointers and the incoming pointers.)

Eventually, following the allocation of an object, the allocation area will be exhausted, and at that point the simulator begins simulating a collection. The first task is to choose the subset of objects that will be subjected to collection (the collected region C). How this choice is made differs between collection algorithms, as described in Chapter 3. The remaining objects will be the uncollected set U.

The simulator finds the roots of the collection as follows. First, all objects in C that are not *known-dead* are roots. These objects would be reachable from the stack and globals at this point in actual execution. Second, all objects in C which have an incoming pointer from U are roots. These objects must be assumed live because *all* of U is assumed live in region-based collection.

The simulator then computes the transitive closure of the points-to relation over the root set within C, using a simple worklist mechanism. The result is the survivor set S. Data structures

corresponding to the garbage set $G = C \setminus S$ can now safely be discarded from the global set. Finally, the sum of the sizes of objects in S is added to the running sum of volume copied, and a collection counter is incremented.

The available allocation area increases by the amount freed, that is, the sum of the sizes of objects in G. If this amount is still not greater than zero, the simulator announces that the collector has failed.

As we have seen, the collection simulator keeps track of the total volume of allocated objects, as well as the total volume of survivor objects over all performed collections. By definition, the total volume of survivor objects is the measure of the copying cost of collection. The mark/cons ratio μ is also directly available as the ratio of the total volume of survivor objects to the total volume of allocated objects.

4.3.2 Age-based simulation

In age-based simulation, the relative order of object allocation remains the (logical) order of objects in the heap, and determines collection decisions. Therefore, the global set is implemented as a (doubly-linked) list. New allocation adds objects to the young (right) end of the list. The choice of the collected region is restricted to selecting a contiguous sublist C of the global list. The collection then finds the sublist of survivors S, which is spliced back into the global list in the place which C occupied.

When simulating age-ordered schemes, the time of allocation serves as a unique timestamp, and membership in a sublist can be determined by timestamp comparison instead of a full-fledged set-membership test; other manipulations are simplified as well.

For renewal-age schemes, S is attached past the young end instead. The objects in S receive *renewed* timestamps.

4.3.3 Block-based simulation

We implemented a prototype version of the block heap organization for age-based garbage collection, as outlined in Section 3.2. This prototype runs on 32-bit Sun SPARC machines and

does not use the design for large address spaces of Section 3.2.4. It is heavily instrumented in order to record all collector actions, as well as all the write barrier actions.

In order to examine how the block implementation works for the same traces that were examined using object-level simulation, we construct a *pseudomutator*: a program that accepts a trace input in our standard format, and performs the same heap-related actions that the original traced program did. We then integrate the pseudomutator with the (various) garbage collectors in the block implementation prototype. Because the computational aspects of the program are replaced with table lookup in the pseudomutator, the combined system remains a simulator, rather than an accurate replica of the original program. Therefore we are content with obtaining thorough statistics of copying costs (as counts of words copied) and pointer-management costs (as counts of different write-barrier and remembered-set processing operations).

CHAPTER 5

EVALUATION: COPYING COST

In this chapter we focus on the copying cost of collection to the exclusion of other cost factors. We look at the measured copying cost of the various age-based algorithms, including the traditional generational youngest-first collectors and the newly proposed deferred older-first collector. We examine the contribution of excess retention to the copying cost, and search for the lower bounds of copying cost given the constraint of heap size, by looking at a hypothetical optimal collector and at different tentative adaptive collectors.

5.1 Method for evaluating different configurations of a collector

The copying cost of a given garbage collection scheme depends primarily on the size of the available heap space and the settings of configuration parameters. The available heap space is described by a single number, V, since in this study that space is constant. For collection schemes with fixed size of the collected region (FC), that size is the only configuration parameter, and is conveniently expressed as a fraction g of total heap volume V, thus $g = \frac{C}{V}$.

For each benchmark, a suitable set of values is chosen for V. The heap volume must be at least equal to the maximum amount of live data in the program. The performance of any collector, however, can be expected to be extremely poor if V is too close to this minimum. We let V assume up to 9 discrete values between 1.2 and 6 times the minimum, in geometric increments of 20%. Note that fewer than 9 heap sizes are reported for some benchmarks: when the criterion for benchmark relevance discussed above (more than 10 non-generational collections) is not met for the largest tested heap sizes, they are not reported. A suitable set of values is chosen for g as well: we let the fraction assume 20 discrete values between 0 and 1.

For each pair of V and g values, we performed a simulation of the benchmark. For a given heap size V, by varying the configuration parameter g (how *much* data is collected each time), we explore its effects on copying cost, within a fixed strategy of *where* to choose the data to collect.

Similarly, for the generational schemes, specifically 2GYF and 3GYF, the fraction of heap space dedicated to the nursery is the primary configuration parameter. For 2GYF it is the only parameter for a given heap size, and for 3GYF there is an additional parameter in the choice of division of the remainder of the heap between the middle and the oldest generation, but, as we shall see, its influence on performance is less pronounced.

5.1.1 Results

We present the results for each benchmark in turn, and for each benchmark we give a series of plots, ordered by increasing heap size. For each heap size, we show in separate plots (a) the performance of the FC schemes as a function of the fixed fraction collected, and (b) the performance of the GYF schemes as a function of the nursery size.

Each of the figures in this section (Figures 5.7–5.110) consists of two plots, on the left (a) the plot for FC schemes and on the right (b) the plot for GYF schemes. The vertical axis (the ordinate) has the same meaning in both: it gives the relative mark/cons ratio ρ, which is the mark/cons ratio of a particular scheme relative to the mark/cons ratio of the non-generational collector for the same heap size. The scale on the vertical axis is the same for FC and for GYF, and for all heap sizes for the same benchmark. The horizontal axis (the abscissa) in the FC plots gives the size of the collected region expressed as the fraction g of heap size. In the GYF plots, the horizontal axis gives the size of the nursery as a fraction of heap size. It would be misleading to show both in the same graph, since the size of the collected region in GYF is occasionally the whole heap. In plots (a), we have drawn the curves for the following schemes:

FC-TOF, FC-TYF, FC-DOF, FC-DYF, and FC-ROF.[1] In plots (b), we have drawn a curve for the scheme 2GYF, whereas the measurements for the 3GYF scheme are presented as a scatter plot, since the same nursery size can be combined with different divisions of the remaining space into the two older generations. These plots permit us to analyze how the choice of configuration affects the copying cost. Furthermore, for FC schemes, the configuration determines the maximum amount that can be copied on each collection, thus it (approximately) bounds pause times.

5.1.1.1 The FC-TOF collector

We observe that in all benchmarks save the two Tree-Replace programs, FC-TOF performs poorly. Its copying cost is generally higher than that of non-generational collection: $\rho > 1$. When the size of the collected region is close to the whole heap size, FC-TOF performs as well as non-generational, which is to be expected, but when the collected region is reduced, the collection cost rises dramatically, and ultimately, the collector fails. This result is easily explained by the presence of some amount of permanent data in the heap: permanent objects are the oldest objects, hence the collector copies them repeatedly, and if the collected region is so small that it contains nothing but permanent objects, the collector finds no garbage and fails.

For the programs Tree-Replace-Binary and Tree-Replace-Random, on the contrary, FC-TOF is the best scheme, and its copying cost is as low as one half that of non-generational collection. In these (admittedly synthetic) benchmarks, the amount of permanent data is relatively small—only the first several layers of a tree from the root are permanent. Moreover, the subtrees are chosen for replacement *at random*, which means that older subtrees do eventually become garbage. Our intuitive argument in Chapter 1 and Figure 1.1, that the longer the collector waits the more likely it is that an object is garbage, holds in these programs.

---

[1] If a curve is entirely missing from a plot, it is because no configuration of that scheme successfully completes execution. (See Section 4.3.1.)

5.1.1.2 The FC-ROF collector

The FC-ROF collector behaves just like the FC-TOF collector for large collected region sizes. However, at smaller collected region sizes, the FC-ROF collector diverges from FC-TOF, and is sometimes able to avoid its poor behavior. For instance, in benchmark Swim, with a heap size of 38733 words (Figure 5.53(a), p. 158), whereas the performance of FC-TOF degrades rapidly as g decreases below 0.6, FC-ROF only degrades to $\rho = 1.5$, and then returns to lower levels—but never below 1. An interesting reversal occurs for the two programs Tree-Replace-Binary and Tree-Replace-Random, where FC-TOF works well, and FC-ROF degrades precisely when the size of the collected region is reduced below 0.6 (Figure 5.80(a), p. 169). This phenomenon deserves further investigation.

5.1.1.3 The FC-TYF collector

The FC-TYF collector joins FC-TOF and FC-ROF in the class of collectors that only work well when the collected region is nearly the whole heap. Otherwise, this collector almost always performs worse than the non-generational collector. This is not surprising; if this collector could work in a steady state, it would never examine objects to the left of its collection window. In other words, once a young object survives one nursery collection, it is "tenured". It is surprising that this collector works at all, and this must be due to the fact that programs show phase behavior and do not enter a truly steady state.

5.1.1.4 The FC-DOF collector

The FC-DOF collector is consistently better than other FC schemes, except on the two programs Tree-Replace-Binary and Tree-Replace-Random. It generally works better with *smaller* collected region sizes, except for Toba and Lambda. For many examined programs there exists, for sufficiently large heaps, a characteristic region size below which the FC-DOF collector works particularly well. This passage from acceptable performance to exceptionally good performance is sometimes abrupt, as for StandardNonInteractive at region size $g = 0.9$ (Figure 5.25(a), p. 145), and sometimes gradual, as for Richards, when region size is reduced from

$g = 0.8$ to $g = 0.4$ (Figure 5.85(a), p. 171). The FC-DOF collector is the best among the FC schemes, and we shall investigate its behavior in greater detail in the remainder of this chapter and in Chapter 6.

5.1.1.5 The FC-DYF collector

The FC-DYF collector usually performs better than non-generational collection. However, it is always substantially worse than FC-DOF, from which it differs only in the direction of collection window motion. Its copying cost is remarkably insensitive to the region size parameter for those values where the collector succeeds; these are, however, limited to medium values, whereas for small windows as well as for large windows, this collector is prone to failure. Both the poor performance and the failures (as the ultimate manifestation of poor performance) are caused by the fact that the collection window sweeps the heap too fast. The intuition that survivors of one collection should not be in the collected region of the following collection conspires with the younger-to-older window motion direction in FC-DYF to cause fast window motion, and too many visits to the far ends of the heap where there are many survivors.

5.1.1.6 The GYF collectors

The curve of the 2GYF collector copying cost and the patterns of the 3GYF scatter points reflect the presence of different modes of operation of the generational collector, corresponding to different numbers of younger-generation collections between successive older-generation collections (Figure 5.50(b), p. 157). The resultant 2GYF copying cost is therefore sometimes lowest for medium values of nursery size, as in InteractiveAllCallsOn (Figure 5.12(b), p. 140), sometimes it is lowest for small values of nursery size, as in Swim (Figure 5.50(b), p. 157), and sometimes it is lowest for *large* values of nursery size, as in Lambda-Fact6 (Figure 5.44(b), p. 154).

It will also be observed that the scatter points for 3GYF are clustered closely, and usually not far below or above the line corresponding to 2GYF. Thus, the copying cost of 3GYF is usually comparable to that of 2GYF. Occasionally we see a configuration of 3GYF with only

half the copying cost of 2GYF with the same nursery size, as in Lambda-Fact6 (Figure 5.45(b), p. 154); on the other hand, there are programs where no 3GYF configuration is better than 2GYF, as in Toba (Figure 5.102(b), p. 179), hence the added overhead[2] of 3GYF is only detrimental.

5.2 Method for comparing various collection schemes

We now summarize the findings of the preceding section. In order to compare different collection schemes, we shall restrict each to operate within the same heap size, but we shall let it assume the *best* configuration. In other words, we give each scheme the benefit of the best static choice of the size of the collected region, or the sizes of the various generations. The plots in Figures 5.111–5.124 (pp. 183–190) show the copying cost for these best configurations. Along the horizontal axis is the heap size allotted, and along the vertical axis the relative mark/cons ratio ρ. There are 8 curves in each plot, for the collection schemes FC-TOF, FC-TYF, FC-DOF, FC-DYF, FC-ROF, NGYF,[3] 2GYF, and 3GYF.

In the plots for Interactive-TextEditing (Figure 5.112), StandardNonInteractive (Figure 5.113), HeapSim (Figure 5.114), Richards (Figure 5.121), and Bloat-Bloat (Figure 5.123), there is a clear separation between the schemes FC-TOF, FC-TYF, FC-DYF, and FC-ROF, which exhibit high copying cost, and the schemes FC-DOF, NGYF, 2GYF, and 3GYF, which exhibit low copying cost. In other programs the separation is not as clear, and indeed for Tree-Replace, the FC-TOF and FC-ROF schemes work best.

There is not a uniform dependence of ρ on heap size (for a specific collection scheme): whereas in Richards ρ decreases with heap size for the four better-performing schemes, in Bloat-Bloat and Swim it increases. Note that the *absolute* copying cost μ nevertheless decreases—ρ is relative to the cost of non-generational collection, which itself is decreasing. This fact is

[2] Recall the elision of the write barrier at collection time (Section 3.2.2).

[3] Since NGYF has no configuration parameters, it was not discussed in the preceding section. Heap size uniquely determines the value of ρ reported here for NGYF.

evidenced in Figures 5.125–5.138, pp. 191–198, which display the *absolute* copying cost, expressed as the mark/cons ratio μ, for the best configuration of each scheme.

With respect to copying cost, the newly introduced scheme FC-DOF is competitive with generational collectors for all examined programs, and markedly better for some (Interactive-AllCallsOn, Interactive-TextEditing, StandardNonInteractive, and Richards). For Richards with a heap size of 4914 words, the copying cost of 3GYF is 10.37 times higher than that of FC-DOF.

Observing the performance of all the collectors, we note that most programs permit region-based schemes to cut down the copying cost of collection significantly with respect to non-generational collection: for Interactive-AllCallsOn to the fraction 0.13; for Interactive-TextEditing to 0.18; for StandardNonInteractive to 0.045; for Richards to 0.029; and for HeapSim, Swim, Tomcatv, and Bloat to the vicinity of 0.2. However, the copying cost of Toba is not reduced below 0.6, Tree-Replace-Binary and Tree-Replace-Random are only reduced to about 0.5, and the most intransigent Lambda-Fact5 and Lambda-Fact6 are not reduced below 0.7.

5.3 Method for recognizing and measuring the excess retention cost

Let us examine a garbage collector that considers a collected region C smaller than the entire heap, in order to limit the amount of work done at each collection. The maximum copying cost is bounded by the size of the collected region, since in the worst case all objects within it may be live. The exact computation of the set of live objects, however, requires an examination (pointer tracing) of the entire heap, and not just C, at a cost not much lower than the cost of *collecting* the entire heap. Instead, collectors make a conservative approximation: they assume that all objects in the uncollected region U are live, hence that every pointer that crosses from U to C lies on a path from a root, even if that is not actually the case. *Excess retention* is that part of the collection copying cost which is caused by the inaccuracy of this assumption. On a single collection, the excess retention is manifested as an increase in the

volume of survivors. Since the volume freed is correspondingly reduced, the next collection must take place sooner, and the overall number of collections is increased.

To measure how large the excess retention part of the copying cost is, we devised a variant of collector simulation (deployed in all the simulated schemes) that does not assume liveness for the uncollected region. Instead, the survivor set S among the collected objects C is precisely the set of objects that are not *known-dead*. This manner of simulation is possible because our trace contains accurate liveness information, and can thus act as an oracle guiding the collection. The difference between the actual copying cost, and the copying cost as it would be with this oracle, gives the excess retention cost.

5.3.1 Results

Each of the figures for this section (Figures 5.139–5.242, pp. 199–243) consists of two plots, on the left (a) the plot for FC schemes and on the right (b) the plot for GYF schemes. The vertical axis (the ordinate) shows the excess retention for the configuration, expressed as the ratio of the actual copying cost to the oracular copying cost. Note that the variation of the excess retention ratio is so large that we could not maintain the same scale in the plots, thus visual comparisons between FC and GYF are discouraged. The horizontal axis (the abscissa) in the FC plots gives the size of the collected region expressed as the fraction g of heap size. In the GYF plots, the horizontal axis gives the size of the nursery as a fraction of heap size.

Let us first note that in some rare configurations, both for the FC and for the GYF schemes, the excess retention ratio is below 1, for instance in Interactive-AllCallsOn, Figure 5.141, p. 200. It may seem odd at first glance that the collector without the benefit of an oracle performs better than the one with it, but recall that, if the oracle makes an actual difference in the determination of the survivor set S, then the two collectors will perform their collections at different instants, and, as we discussed in Section 4.2.2.2, the choice of collection instants introduces a slight "random" effect. Having dispatched this anomaly, we note that excess retention displays widely different behavior for the several benchmarks, and for different schemes.

The excess retention of the GYF schemes is low, below 10% (ratio below 1.1) for most programs, with Lambda (Figures 5.166–5.181, pp.211–217), Tree-replace-Random (Figures 5.205–5.212, pp.228–230), and Toba (Figures 5.234–5.242, pp.240–243) as exceptions.

Excess retention does play a critical role in determining the performance of collectors for some programs. For instance, for Lambda-Fact6, we noticed that none of the collectors has a copying cost much lower than non-generational (Figure 5.48, p. 155), and now we can observe in the corresponding plot of excess retention (Figure 5.180, p. 216) that for a nursery size of one-half heap size, the excess ratio of 2GYF is 2, hence with an oracle the copying cost would be halved from $\rho = 1.5$ to $\rho = 0.75$. But the effect on FC-DOF is far stronger: the excess ratio is 50 for collected region size equal to 0.2 of heap size, hence with an oracle the copying cost would be reduced from $\rho = 3$ to $\rho = 0.06$. The previously noted intransigence of Lambda-Fact6 with respect to copying cost thus has its origin in a pointer structure that causes very high excess retention for those schemes (GYF, DOF) that we found to work well on other programs.

On the other hand, consider the benchmark Richards with a heap size of 4032, for which the copying costs are shown in Figure 5.85 on p. 171, and the excess retention in Figure 5.217 on p. 232. The actual copying cost of FC-DOF decreases as the size of the region collected is decreased from 0.8 down to 0.3, *even though* the excess retention ratio increases sharply from 1 to 8. Meanwhile the 2GYF collector enjoys negligible excess retention, yet its copying cost is much higher than that of FC-DOF.

In summary, excess retention sometimes dominantly influences performance, but sometimes its effects are negligible. Whereas it could have been surmised that schemes that collect regions in the older parts of the heap suffer from prohibitively high excess retention because of the supposed predominance of younger-to-older pointers, this case does not occur in our benchmarks.

5.4 Methods for examining the lower limits of copying cost and the feasibility of adaptation

We have seen that the GYF and FC-DOF schemes compete for lowest copying cost, and that FC-DOF is sometimes considerably better. We now examine if copying cost can be reduced further, and how. We remain within the class of FC schemes—thus each collection collects a region of fixed size—but now we allow more latitude in the choice of where the collected region lies within the heap.

5.4.1 Locally-optimal copying cost

We described the locally-optimal schemes in Section 3.1.3. It is straightforward to simulate them in an object-level garbage collection simulator. On each collection, we place the collection window at all possible positions in the heap, and for each position we perform a collection as usual, except for the final step of deleting the garbage found. Thus for each possible position we calculate the corresponding mark/cons ratio, then choose the position with the lowest one, and complete the collection with the window at that position.

The number of possible positions is at most the number of objects in the heap, and somewhat smaller because the window must wholly lie within the heap. However, it can be a large number if the heap consists of many small objects, hence this simulation can only be carried out for smaller benchmarks. In plots in Figures 5.243–5.266, pp. 244–253 (at the end of this chapter), we show the copying costs of the locally optimal schemes together with the age-based schemes considered before, for three representative benchmarks, StandardNonInteractive, Lambda-Fact5, and Tree-Replace-Random.

For StandardNonInteractive, the locally optimal collector only matches the performance of FC-DOF, and is in some configurations not as good as FC-DOF (recall from Section 3.1.3 that FC-OPT is not necessarily optimal globally!). For Lambda-Fact5, on the other hand, FC-OPT is significantly better than any of the realistic FC collectors, and any of the generational collectors, and achieves a copying cost of less than half of the non-generational collector's

cost. The situation is similar for Tree-Replace-Random, where FC-OPT has much lower cost than FC-TOF, the best realistic scheme considered for this benchmark. The explanation is straightforward in this case: the collected region is positioned to include exactly the objects of the subtree that has just been replaced (provided that the size of the collected region is not much larger than the subtree).

5.4.2 Window motion

In order to understand the behavior of FC collectors, we observe how the position of the collected region within the heap changes from one collection to the next. We call this *window motion*. We shall use window motion analysis to guide the design of adaptive collection in Section 5.4.5.2. A window motion plot (such as Figure 5.1, p. 132) shows the location of the collection window in the heap in successive collections. The window is contained between the two marks of the old end and the young end, shown along the vertical axis. The horizontal axis show the progression of collections, and is gauged according to the amount of allocation, so that the window motion graph can be compared against the live profiles (Section 4.2.3) and the detailed heap profiles (next section). The *horizontal displacement* of the window from one collection to the next equals the amount allocated between collections. The *vertical displacement* of the window, for the DOF regime of window motion, equals the amount of survivors of the preceding collection. Therefore, for DOF, the *slope* of the window motion curves equals the instantaneous mark/cons ratio. Hence good performance shows as shallow slope, and ideal performance would show as a flat window motion curve.

5.4.3 Demise point analysis

Our fully accurate trace permits simulation and evaluation of any garbage collection algorithm. The algorithms differ in the choice of the instants when they perform collections, and, at each collection, the choice of the collected region. These differences cause the heaps to contain different amounts of garbage data and in different positions. The sets of live objects, however, are necessarily the same. Objects in the heap are ordered according to their time of

allocation, hence the live objects are not only equal as a set, but also as an ordered list, across all collectors.

When the collection algorithm decides which region it should collect, its goal is to choose that region which has the greatest garbage content. We have observed that garbage collectors differ in the amount and position of garbage that they keep in the heap. However, the component of garbage that just came into being—objects that have most recently died—is equal for all collectors. Indeed, if a collector succeeds in collecting objects immediately after they become garbage (or very soon), that will be the only component of garbage. Therefore, the focus of our method is to identify when and where fresh garbage arises.

To answer the temporal question, we imagine a collector that *immediately* discovers all objects that become garbage, and immediately collects them. Clearly, the information in the trace as described in Section 4.1 suffices to simulate this collector. To answer the spatial question, recall that ordering by age is assumed. Therefore, in a linear list of objects currently in the heap, the collector can mark those it has just discovered are garbage, and report their position before collecting them away. The position is given as the number of words from the young end of the heap, for each word of a garbage object.

Since the purpose of the method is to guide designers of garbage collection algorithms in their analysis of collector performance, we turn now to the task of presenting visually the findings of the described ideal collector.

5.4.3.1 Visualization: demise maps

We observed that the ideal collector reports the demise of each object as soon as it happens. More precisely, it reports the demise of each *word* of the object, giving the time of demise exactly, as the amount of allocation in the program up to that point. It is then natural to construct a two-dimensional grid, with one dimension corresponding to the allocation time, and the other to the position of the word in the heap, and the grid point is set if the word at the corresponding heap position died at the corresponding time. We lay the time along the longer,

horizontal, axis, and heap position along the vertical axis. The heap position is measured from the *young*, most recently allocated end of the heap in age order. A demise point is shown as a black dot. Thus we have constructed a *demise bitmap*.

In practice, however, we must take an additional step to produce visual displays of demise. Note that the dimensions of the demise bitmap are (Total words allocated) × (Maximum words live), which, even for the relatively small benchmarks in our suite, can be of the order $10^6 \times 10^8$. Such a large bitmap cannot be graphically rendered directly. Instead, we divide both the time and the space axis into clusters, compute the number of set bits of the demise bitmap in each cluster, and assign greyscale levels to each cluster accordingly. Having considered the capability of the rendering device and the size of the final images, and having experimented with different granularities, we settled on a 100 × 660 greyscale map. Thus obtained demise greyscale maps for our benchmark are presented in Figures 5.267–5.280 on pp. 254–267. Each panel is in three aligned displays: the middle display shows the demise points, while the top and bottom display show heap profiles, which we presently discuss (the top display shows the curves of equal time of allocation; and the bottom display shows the curves of equal age).

5.4.3.2 Visualization: heap profiles

The demise map faithfully presents temporally local information. We know which words have just died in the sense that the map shows *where* they were. It does not tell us the identity of these words—at which point were they allocated. However, the ideal trace can be used to produce a telling visual display of this information, in the form of a *heap profile*. The duration of program execution is divided into a number of equal-sized segments, and the heap profile tracks the motion of each segment in the heap from the time of allocation onwards. Since the heap is age-ordered, the objects allocated during one segment remain contiguous in the heap. Thus it is possible to draw nonintersecting lines of constant allocation time for each of the times at the boundary of two allocation segments. If we again show the heap positions with youngest end at the bottom, then subsequent segments are stacked below previous segments

in a banded plot. The height of a band indicates the currently surviving amount of data from a given segment of allocation. The total height of all bands indicates the total amount of live data in the heap.

The information in this plot is, in principle, equivalent to that in the demise map, but it has different visual properties. For instance, in benchmark Interactive-AllCallsOn, Figure 5.267, it is easy to see a correspondence between the sharp fall of the lines in the heap profile and the stripe of demise points at time 10200. However, it would be difficult to discern in the heap profile a corresponding feature for the stripe of demise points at time 1000, because it happens when the lines in the heap profile are mostly rising. Thus the two forms of display are complementary.

Lastly, the bottom displays of Figures 5.267–5.280 show the heap profiles using lines of constant *age*, allowing us to observe the relative participation of younger and older objects in the heap, as execution progresses.

Heap profiling is not a new concept. It has been used in analyzing heap usage in lazy functional programming languages [Runciman and Wakeling, 1992; Runciman and Röjemo, 1995; Sansom, 1994; Sansom and Peyton Jones, 1994; Röjemo and Runciman, 1996], where, however, the grouping criterion of interest is not the age of objects, but the function-point that allocates them. We earlier proposed a related three-dimensional visualization based on object age [Stefanović, 1993a; Stefanović and Moss, 1994].

5.4.3.3 Visualization: position mortality

The demise maps and heap profiles provide a graphical representation of the time-varying behavior of a program, but we nevertheless desire a time-averaged summary. Even if the demise maps show that garbage will occasionally arise anywhere in the heap, we want to know where most of it should be expected, in the hope that a collector might work well by concentrating its efforts there. A useful summary is obtained by counting the number of demise points that occur at each heap position. Note that if we ascribe demise not to an object, as

we usually do, but instead to the heap position the object occupies, then we can speak of *position* mortality, as the likelihood that the word at certain position (whichever that word is) will become garbage upon the next time increment. In the frequency interpretation of probability, this likelihood is exactly given by the count of demise points. We show the plots of this quantity in Figures 5.281–5.294 on pp. 268–275. The horizontal axis corresponds to heap position, with the young end at 0. The vertical axis, on a logarithmic scale, gives the number of demise points at each heap position.

5.4.4 Case studies

We now look in detail at the spatio-temporal behavior of benchmarks Richards and Lambda-Fact5. In addition to discussing the information directly available in the graphs obtained by the method of the preceding section, we shall relate it to the object lifetime statistics, and the observed performance of different age-based garbage collection schemes. This analysis will serve as the basis for improving the copying cost of collection in the following section.

5.4.4.1 Benchmark Richards

The benchmark Richards is characterized by a small amount of live data in comparison with its long duration. The average lifetime of objects is short, which is reflected in the strong band of demise points (black) in the demise map (Figure 5.277) along the bottom edge of the map, corresponding to the demise of recently allocated objects. A long-term periodic pattern is clear as well, both in the demise map, and in the heap profile, with about four periods (of duration approximately 900000 words) completing. The end of a period is marked in the demise map by a sudden demise of a large number of words in the mid-to-older part of the heap.

The heap profile is revealing: the main feature is the wide band of oldest data, which consists of objects allocated entirely within the first segment or about 60000 words. Once the size of this segment has dropped to about 500 words, it remains constant for the remainder of program execution. In other words, these are the objects that the program uses permanently:

its “static” data. It is worth noting that these objects represent a large fraction of the total live amount, above one third. Indeed, in almost all the benchmarks we examined, there is a significant amount of static data. In addition to the band that survives from the very start of the program, within each period there is an additional accreting set of bands, which die together at the end of their period. For the duration of the period, these bands also act as static data. Underneath we observe a region of objects that survive a short time, enough to reach position 200-300 in the heap, and then die.

The presence of a large quantity of static data as the oldest data in the heap has a strong detrimental effect on the performance of garbage collector algorithms that ever choose to collect the older region of the heap. It is remarkable, however, that the FC-DOF algorithm, which repeatedly visits the oldest part of the heap, once for every rightward sweep (Section 3.1.1), works quite well on the Richards benchmark, and outperforms all examined age-based schemes, including generational collection—in spite of the presence of static data. It does so by sweeping the static data *fast*, and then focusing on the region of high demise. In Section 5.4.5.1, we modify that algorithm to avoid the static data and find that its copying cost improves further.

5.4.4.2 Benchmark Lambda-Fact5

The benchmark Lambda-Fact5 is of particular interest because we found that none of the examined garbage collection algorithms performs well on it. Examination of the heap profile, Figure 5.271 reveals that there is a very large fraction of static data, which hampers older-first algorithms. The static data, allocated during the first 10% of program execution, account for over half of the live amount present in the heap. In addition, there is some accumulation of objects allocated later on, seen as an increasingly wide band of narrowly spaced lines.

On the other hand, the demise map shows significant demise areas in middle heap positions, especially as a periodic pattern during the latter half of program execution. The presence of these demise points precludes the dominance of points in the very youngest part of the heap

and hampers youngest-first algorithms, such as traditional generational collection. The plot of the distribution of demise points by position in Figure 5.285 emphasizes this observation.

Generational collection, unless given a very large heap space, works poorly with small nursery (youngest generation) sizes because too much data is promoted out of the nursery (Figure 5.36(b)); if the nursery size is increased, the above-mentioned demise regions are included, and the performance improves, but even then it only begins to approach non-generational collector performance (when the nursery is so large that the collector behaves almost as a non-generational collector). Similarly, age-based collectors with constant collected region size perform poorly on this benchmark (Figure 5.36(a)), no better than the non-generational collector. However, the hypothetical FC-OPT collector is capable of markedly better performance, with copying cost only 27% of the non-generational for heap size 11402 (Figure 5.254).

5.4.5 Adaptive FC collection

In this section we examine how to improve the performance of collection by modifying the idea of sweeping the heap with the collection window in successive collections. We are guided by the demise map, and by the observed motion of the collection window in the locally-optimal collector. We undertake exploratory case studies of *adaptive* policies within the class of age-based collectors with a fixed collected region size. On the example of the Richards benchmark we shall examine how to remove the permanent data of a program from consideration, and on the example of the Lambda-Fact5 benchmark we shall examine how to adjust the position of the collection region adaptively in response to collection results. In both cases, we shall find it possible to reduce the copying cost of collection over fixed policies.

5.4.5.1 Eliminating the "static" data in Richards

We noted in Section 5.4.4.1 that the presence of a substantial amount of permanent, "static" data in the oldest region of the heap degrades the performance of DOF collection, because collections that examine the oldest region find little garbage, or even fail if they find no garbage. If, however, the collector knew that the oldest region contains such permanent data, it could

skip over them, never trying to collect them. It would thus be able to sweep over only the part of the heap where there is some object demise, and potentially incur a lower copying cost. The danger, of course, is if the "static" region is incorrectly identified as such: if some objects in the region that the collector never considers do in fact become garbage, then two penalties are paid. First, the space occupied by these objects is not reclaimed, and the collector works with a heap effectively smaller than it needs to be; and second, since these objects are considered live, any pointers they might have into the collected region cause excess retention. These dangers are familiar from the parallel situation of *premature tenuring* of objects in generational garbage collection [Ungar, 1984; Ungar, 1986]. Most programs, however, do have a region of permanent data, and the question is only how big it is.

The collector should not immediately exclude the oldest region. The heap profiles (Figures 5.267–5.280) show that a significant amount of allocation occurs before the permanent data consolidate, and during this initial period, there is garbage to be collected from among the oldest data as well. Hence, we introduce an adaptive thresholding policy to recognize when the oldest region begins to contain mostly permanent data. The collector initially operates in the usual FC-DOF manner. On each collection upon a window reset, i.e., a collection of an oldest region, the survivor ratio for the collection is computed. As soon as the ratio is above a threshold value θ, all subsequent window resets skip the oldest region.

We take the benchmark Richards for our case study, with the heap size of 4032 words. We use a window size of 1088 words, or $g = 0.27$, for which the FC-DOF collector achieves a copying cost of $\mu = 0.03181$. With the same heap size, the NONGEN collector has a copying cost $\mu = 0.3937$, the best configuration of the 2GYF collector has $\mu = 0.2198$ (with nursery size 2056 words), the best configuration of the 3GYF collector has $\mu = 0.1221$ (with nursery size 2214 words), and the best configuration of the FC-DOF collector has $\mu = 0.02975$ (with window size 1572 words, or $g = 0.39$).

Our first experiment is to supply to the collector the size of the region of permanent data. This value can be read off the heap profile, and for Richards it is 490 words. We expect that if θ

is chosen too low, then the region of permanent data will be taken out of consideration too soon, whereas if θ is chosen too high, the region will be excluded too late to improve performance. Experimentation with different values of θ shows that results are not exceedingly sensitive to the choice, as shown in Table 5.1.

Table 5.1. Copying cost dependence on the adaptation threshold

θ	μ
0.2	0.02759
0.3	0.02734
0.4	0.02734
0.5	0.02734
0.6	0.02760
0.7	0.02830
0.8	0.03260

The best range of threshold values, $0.3 \leqslant \theta \leqslant 0.5$ includes the value $\frac{490}{1088} = 0.45$, and results in a copying cost of $\mu = 0.02734$. Thus, it was possible to reduce the copying cost by 14% with respect to the ordinary FC-DOF collector with the same window size, and in fact by 8% with respect to the best configuration of the ordinary FC-DOF collector.

In the second experiment, the collector is not told the amount of permanent data, but tries to guess it using the following heuristic: each time the first collection following a window reset results in a survivor ratio above the threshold, multiply the amount of *survivors* by a fixed fraction φ, and add the result to the current estimate of the amount of permanent data. The collector guesses that the high survivor ratio for this collection arose because there were permanent data in the collected region, and that they were the oldest data in the region. It is willing to subject the remaining fraction $1-\varphi$ of survivors to examination at the following reset. Thus the heuristic has two parameters: the threshold θ and the fraction φ. Note that this heuristic is only able to *increase* the estimate, starting from an initial zero, but never to revise the estimate downward. Therefore the danger is that if θ is too low, or if φ is too high, the oldest region may prematurely be considered permanent. We found that the best values are 0.8 for the threshold θ and 0.5 for the fraction φ, in which case the copying cost is $\mu = 0.029$. This

result leads us to believe that it is possible to devise adaptive schemes to sense the presence and gauge the size of permanent data, although our simplistic heuristic is too sensitive to the choice of the two parameters to be reliably used.

5.4.5.2 Choosing the collected region in Lambda-Fact5

Instead of restricting the window motion to the region recognized as non-permanent data, we can modify the behavior of the DOF collector more subtly. The window motion of DOF is based on the intuitive premise that survivors of a collection should not be subject to the immediately succeeding collection. Therefore the window moved rightward over the survivors (Figure 3.9). This policy has excellent performance when the collection survivor ratio is zero or extremely low (as illustrated in Figure 3.10), which is the case in practice for several benchmarks, including Richards and StandardNonInteractive (Section 5.1.1.4). This policy suffers if the survivor ratio is not very low, however, as in Lambda-Fact5. In spite of the many demise points in the middle range of the heap for an ideal collector (demise points map in Figure 5.271), the survivor ratios in actual runs of FC-DOF are high. In Figure 5.2 we show the measurements of the survivor ratios for each collection of the FC-DOF collector on the Lambda-Fact5 benchmark, with a heap size of 11402 words and a window size of 4446 words, for which a copying cost of $\mu = 1.27$ is achieved. The FC-DOF collector performs a total of 150 collections, and each shows up as a point in the scatter plot. The horizontal axis gives the position of the window (indicated by the amount of data between the old end of the window from the old end of the heap), and the vertical axis gives the survivor ratio of the collection (the ratio of the amount of survivors to the window size). The corresponding window motion diagram is in Figure 5.1. Thus, FC-DOF suffers because its window moves too fast across the middle region where it might encounter acceptable survivor ratios, and is too often reset to the old end, window position 0, where survivor ratios are high. Contrast this with the run of the FC-OPT collector with the same heap size and window size, which achieves $\mu = 0.198$. Its window motion graph is in Figure 5.3, and the survivor ratio scatter plot in Figure 5.4. Ob-

serving that FC-OPT moves its window much more slowly, we shall try to emulate its behavior using the following heuristic window motion policy, called the *floating window*.

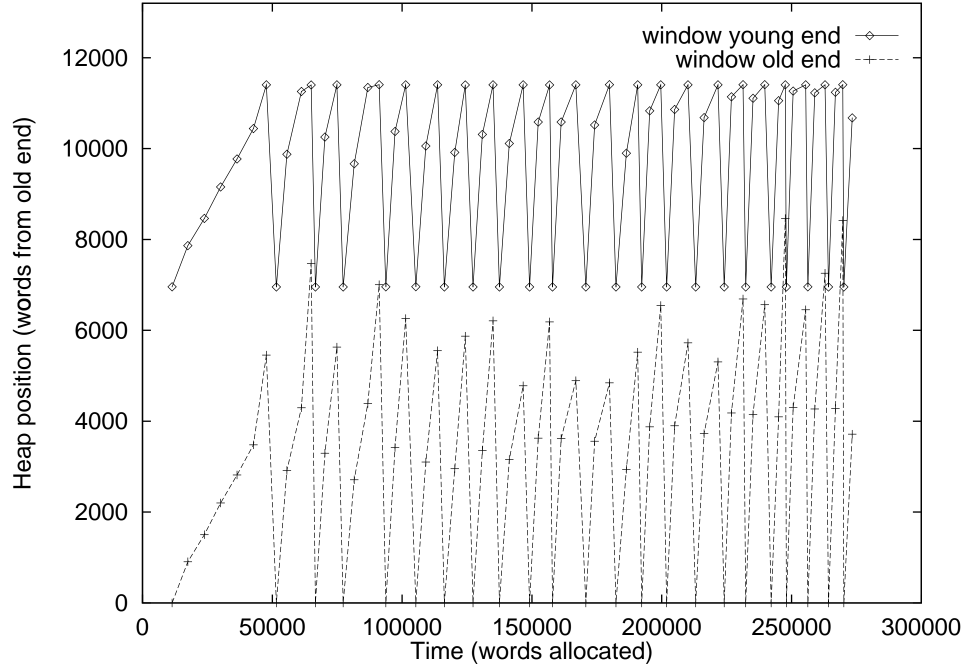

Figure 5.1. Window motion in the FC-DOF scheme.

The position of the window of collection is defined as the amount of data in the age-ordered heap between the old end of the heap and the old end of the window of collection. Let X be the current position of the window of collection. Let W be the size of the window of collection. Upon collection, we find that an amount S has survived out of W. We decide the position for the next collection as $X' = X + \Delta X$ (but resetting X' to zero after the young end of the heap is reached). The increment ΔX is determined as follows. If $S = 0$, then $\Delta X = 0$. Otherwise, note the position p_i of each surviving word in the collection window relative to the old end of the window. The average survivor position is $\bar{p} = \frac{1}{S}\sum_S p_i$. The relative bias is the relative difference between $\bar{p}$ and the value $\frac{W}{2}$ that would be obtained if survivors were evenly spread in the collection window: $r = \frac{\frac{W}{2} - \bar{p}}{\frac{W}{2}}$. Thus $-1 \leqslant r \leqslant 1$. Given an additional fixed external bias e, we set $\Delta X = (r + e)S$. The window is initially placed at X equal to one-half heap size.

In other words, the motion of the window is governed by two forces. An external bias pushes the window in a fixed direction. In particular, the value 1 for the external bias cor-

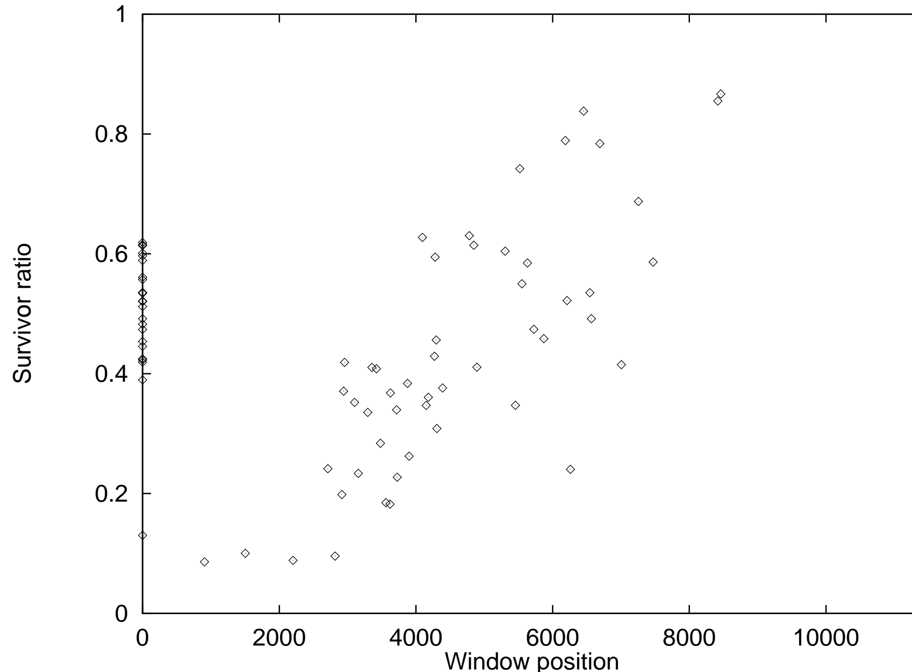

Figure 5.2. Window survivor ratios in the FC-DOF scheme.

responds to the ordinary FC-DOF collector, pushing the window in the direction of younger objects. The second force uses feedback information from the completed collection. Intuitively, if most of the survivors of the collection were found in one part of the window, then the window should be pushed in the opposite direction. For example, if the window straddles the region of permanent data, then most of the survivors will have come from the older part of the window, and it should be pushed towards younger data. We calculate a simple heuristic measure of the desired push as the average position of the survivors within the window. If the average survivor position is left of center, the force is rightwards, and vice versa.

Recall that our test case is the Lambda-Fact5 benchmark, with a heap size of 11402 words and a window size of 4446 words, or $g = 0.39$, for which the FC-DOF collector achieves a copying cost of $\mu = 1.27$. With that heap size, the NONGEN collector has a copying cost $\mu = 0.59$, the best configuration of the 2GYF collector has $\mu = 0.55$, the best configuration of the 3GYF collector has $\mu = 0.56$, and the best configuration of the FC-DOF collector has $\mu = 0.52$. Experiments with different values of the external bias e produce the following results, shown in Table 5.2.

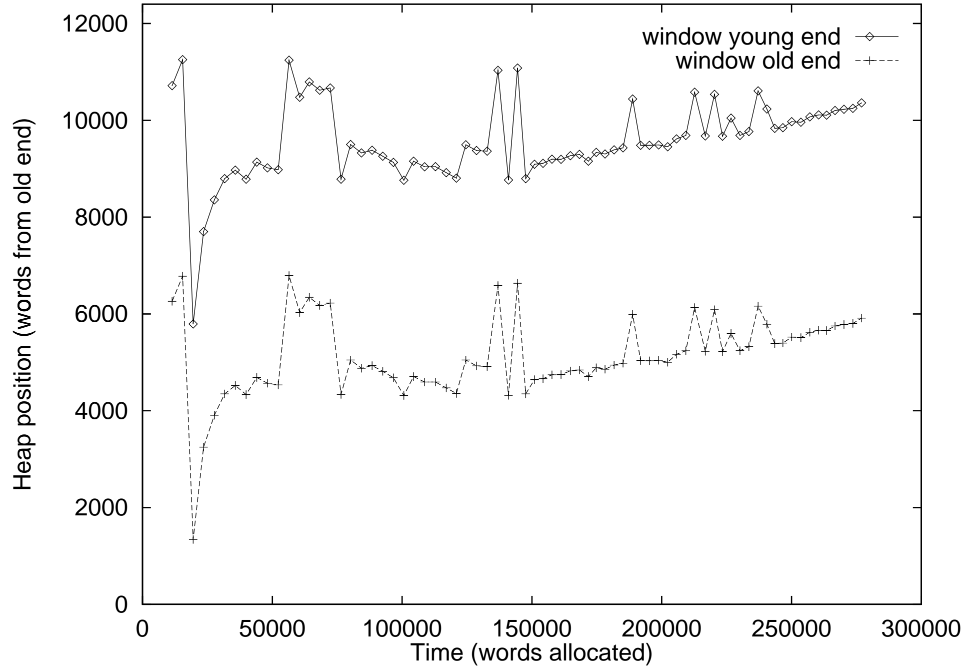

Figure 5.3. Window motion in the FC-OPT scheme.

The lowest achieved copying cost with the floating window policy is $\mu = 0.37$. This is 28% below the best of the fixed schemes for any configuration at the same heap size, namely $\mu = 0.52$ for FC-DOF with a window size of 10135 ($g = 0.88$). We observe the window motion of the adaptive scheme in Figure 5.5, and its scatter plot of window position vs. survivor ratio in Figure 5.6.

Table 5.2. Copying cost dependence on external bias

0.2	0.44
0.3	0.37
0.4	0.40
0.5	0.48

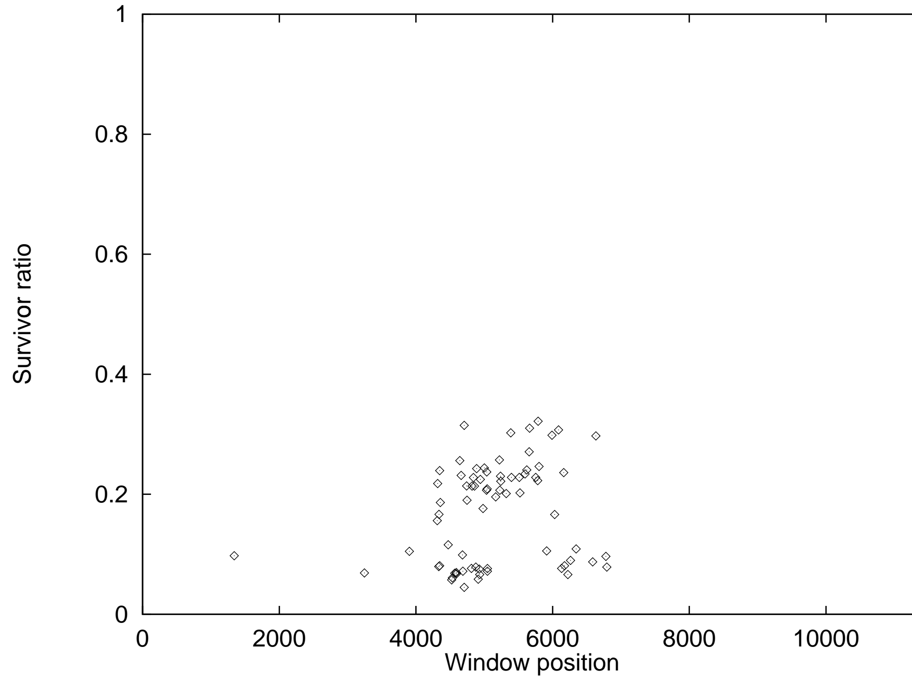

Figure 5.4. Window survivor ratios in the FC-OPT scheme.

The floating window policy is relatively robust with respect to the choice of the external bias, since for the entire region $-0.1 \leqslant e \leqslant 0.5$, the scheme is better than any of the fixed schemes. On the other hand, the FC-OPT copying cost of $\mu = 0.198$, for the same heap size and the same window size, is still another 47% lower.

A final word of caution is in order. We have seen that adaptive variants of FC schemes, and of FC-DOF in particular, can lower the copying cost of collection, and that there exists, for some programs, still more room for improvement, as indicated by the locally-optimal schemes. However, to achieve this further reduction of copying cost requires window motion policies more general than, for instance, the predictable linear sweep of FC-DOF. Recall from Section 3.2.2 that effective pointer filtering at the write barrier exploited the predictability of window motion. Hence, the ultimate reduction of copying cost may well be offset by an increase of pointer management costs.

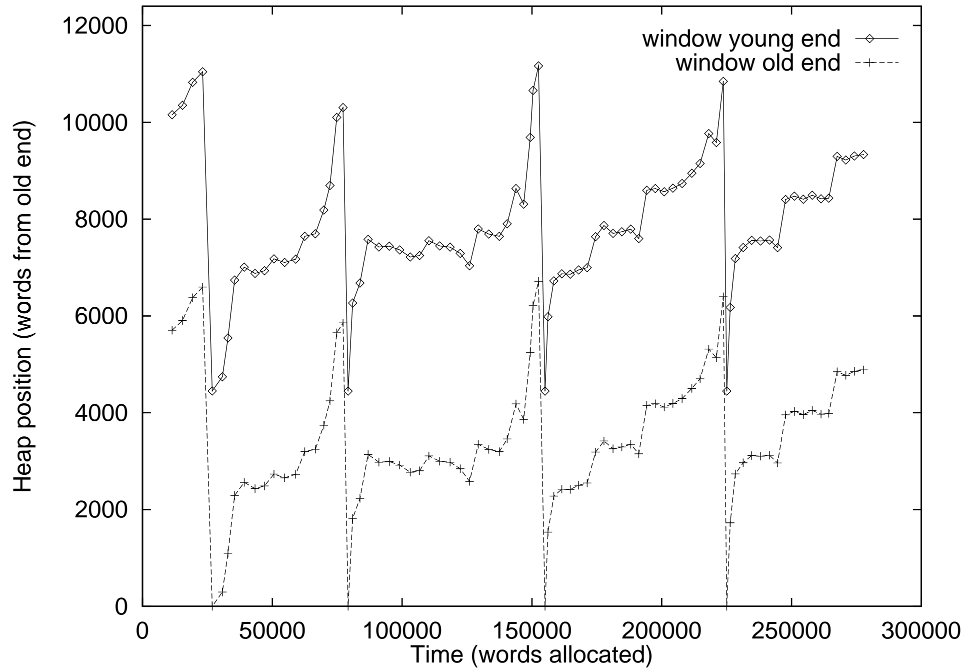

Figure 5.5. Window motion in the adaptive scheme.

5.5 Summary

This chapter examined the copying cost of garbage collection for several age-based algorithms. The main finding is that the promise of low copying cost of our proposed FC-DOF collector is delivered on many actual allocation loads. This result could not be expected given the prior understanding of generational collector performance. Particularly revealing is the fact that excess retention effects, even when very pronounced, do not by themselves rule out using non-youngest-first collectors for our test programs.

The measurements of the performance of generational collectors are interesting in their own right, as they shed light on collector behavior under constraints on total heap size. It is not surprising that small nursery sizes lead to excessive promotion into the older generation, but it is surprising that in many cases the optimal configuration assigns more than half the heap to the nursery. It is possible that more sophisticated generational schemes could perform better—for instance, requiring an object to survive more than one collection in the younger generation before promotion, or, equivalently, dividing the younger generation into steps, possibly combined with adaptive policies, such as Ungar and Jackson's feedback mediation [Ungar and

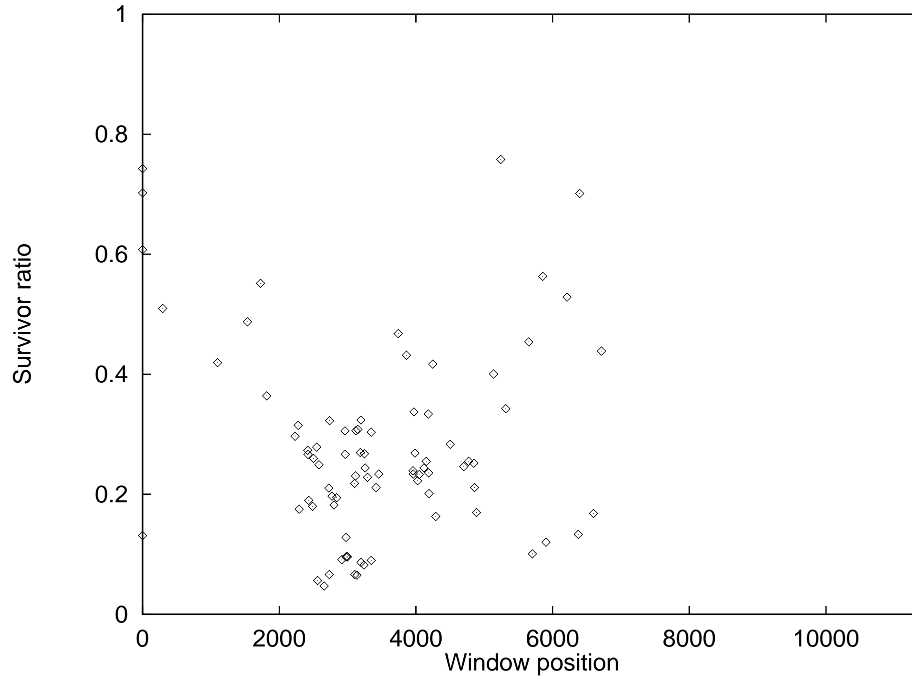

Figure 5.6. Window survivor ratios in the adaptive scheme.

Jackson, 1992]. However, each collection adds to the copying cost, and the final balance cannot be predicted. Unfortunately, the vast dimensions of the space of possible configurations makes it difficult to these collection schemes. (Thus, the selection of their many configurable parameters [Hudson *et al.*, 1991] has largely been a matter of judgement by experience.)

The proposed non-youngest-first schemes can also benefit from more sophisticated configurations. We observed that adaptive positioning of a window of fixed size can reduce copying cost; it is likely that it would be more effective in conjunction with adaptive selection of window size. Most important, however, could be the heuristic discovery of permanent (static) data, and their elimination from consideration by the collector, a task implicitly performed by a multi-generational collector.

CHAPTER 6

EVALUATION: COSTS OTHER THAN COPYING

In this chapter we examine the non-copying costs of collection, focusing on the cost of maintaining the information needed for accurate region-based collection: the write barrier and remembered set overheads. The evaluation uses a realistic, block-allocation collection simulator, based on our prototype implementation. We compare the generational youngest-first collector with the deferred older-first algorithm, which was shown in the preceding chapter to be the most promising with respect to copying cost among the alternatives to generational collection that we considered.

6.1 Method for evaluating the pointer maintenance cost

We use an instrumented version of the block simulator (Section 4.3.3) to obtain the statistics of pointer management operations. We discussed in Section 3.2 the design of pointer management for age-based collection, and noted alternative models of pointer store filtering and of remembered set organization. The actual costs of operations depend on these alternative design decisions. Indeed, the operation counts are not invariant themselves: if two filtering tests are executed in sequence, the outcome of the first influences the number of times the second is executed. The division of labor between the run time and the garbage collection time is also a matter of choice. Here we use for the generational collector the traditional model of operation with a unified remembered set and generational filtering, and we show that it is very efficient. For the DOF collector we use block-local and directional filtering. All of the operation counts reported are accurate for these design choices, while some of them are also universally applicable regardless of the design choice.

For the write barrier, we report the operation counts for pointer stores, and the number of non-null pointer stores. Non-null stores are further divided into stores filtered by the specified filtering mechanism, and those not filtered. The non-filtered stores are divided into unique and duplicate, with respect to the prior content of the remembered set into which the stores are inserted. Note that the write-barrier statistics include both the run time and the garbage-collection time pointer stores.

For remembered set processing at garbage-collection time, we report the number of pointers from the uncollected region into the collected region, as well as the number of remembered set entries actually processed, which can be larger.

6.1.1 Results

In Table 6.1 we report the statistics that are independent of the collection algorithm or its configuration. The columns "Words alloc." and "Ptr. st." repeat the information of Table 4.1. The column "Alloc./st." gives the ratio of the number of words allocated to the number of pointer stores for the program. This value is an indication, albeit crude, of the frequency of pointer manipulations, or the "object-orientedness" of the program, as well as of the expected influence of pointer maintenance operations on overall memory management performance. The last two columns give the number of non-null pointer stores as an absolute number, and as a percentage of all pointer stores. In many implementations of the write barrier, the check for a null pointer is a separate first step. As we can see in our numbers, there are few null pointers, and this test rarely eliminates the pointer from consideration. Hence a write barrier that integrates the null-pointer test into a general address test, as proposed in Section 3.2.4, is to be preferred.

In Tables 6.2–6.15, pp. 295–382 (at the end of this chapter) we report the pointer management statistics for the different configurations of the FC-DOF and the 2GYF collectors. The first group of tables (Tables 6.2–6.8) is for the FC-DOF collector. The first three columns in Tables 6.2–6.8 indicate the configuration. The first column, having values between 9 and 20,

gives the block size: for value k, the block size is 2^k bytes. The second column gives the allotted heap size, in terms of blocks. The third column gives the size of the collected region (the window size), also in terms of blocks. The fourth column gives the absolute copying cost as the number of words copied. The fifth column gives the number of collector invocations. The sixth column gives the number of remembered set insertion operations at the write barrier, i.e., the number of pointer stores that were *not* filtered out. The seventh column gives the number of insertion operations that are not duplicates, and hence actually add entries to remembered sets. The eighth column gives the *sum* of the sizes of all remembered sets processed at garbage collection time (i.e., the sets belonging to blocks within the collected region). The ninth column gives the sum over all collections of the sizes of filtered unions of sets within the collected region.

The design used to produce the statistics is the following. Each block has its own remembered set (Section 3.2.2). The write barrier code is executed on every pointer store, both at run time and at garbage collection time. The write barrier consists of three filtering checks: first,

the check for null pointers; second, the check for block-local pointers; and third, the directional check (as in Figures 3.15 and 3.16). If none of the checks eliminates the pointer store, then the write-barrier code inserts it into the remembered set of the pointer target block, and adds it to the tally for table column six, “W.b. insert.” The remembered set may already contain an entry recording the same pointer source address; otherwise, a new entry is added to the remembered set, and to the tally for table column seven, “W.b. add.”

At collection time, following the processing of global roots, the collector processed the remembered sets of the blocks in the collected region one by one. Table column eight, “R.s. proc,” reports the sum of the sizes of all remembered sets processed over all collections. On the other hand, the sum of the sizes of remembered sets for the collected region can be greater than the number of pointers actually crossing into the collected region from the uncollected region. The latter number is computed as the union of the remembered sets involved, less any pointers that have both source and target in the collected region. The sum of these numbers over all collections is reported in column nine, “R.s. proc.”

The second group of tables (Tables 6.9–6.15) is for the 2GYF collector. The first four columns in Tables 6.9–6.15 indicate the configuration. The first column gives the block size, the second column gives the allotted heap size in blocks, the third column gives the size of the younger generation (the nursery) in blocks, and the fourth column gives the size of the older generation in blocks. The fifth column gives the absolute copying cost as the number of words copied. The sixth column gives the number of collector invocations. The seventh column gives the number of remembered set insertion operations at the write barrier, and the eighth gives the number of these that are not duplicates. The ninth column gives the sum of the sizes of processed remembered sets.

The design used to produce the statistics is the following. There is a single remembered set, and it records the pointers from the older generation into the younger generation. The write barrier code is executed on every pointer store at run time. No write barrier is needed at garbage collection time, because, with only two generations, all objects are in the oldest

generation following a collection. The write barrier consists of two filtering checks: first, the check for null pointers; and second, the generational check. If neither filter eliminates the pointer store, it is inserted into the remembered set, and added to the tally for column seven, "W.b. insert." If the pointer source is not already present in the remembered set, a new entry is added to the set, and to column eight, "W.b. add."

At collection time, the collector processes the single remembered set. Table column nine, "R.s. proc", reports the sum, over all collection, of the sizes of the remembered set. There is no need for a "R.s. union" column for 2GYF, because its meaning is subsumed by "R.s. proc."

Each row of a table corresponds to one configuration of a collector, and thus to one simulation run. The configurations are ordered by block size, and for each block size, they are ordered by heap size. For a given heap size, the configurations are ordered by the size of the collected region (in the case of FC-DOF), and by the size of the younger generation (in the case of 2GYF).

Certain rows are printed in boldface for ease of reference in both the FC-DOF and the 2GYF tables; we shall use these configurations as examples to discuss the comparative costs of the two schemes.

6.1.2 Block size

We first examine the effect of block size on copying and pointer management costs. For the FC-DOF collector, we find that increasing the block size reduces the operation counts for the write barrier and remembered set processing. Consider benchmark Lambda-Fact5 in Table 6.4, p. 310. We shall compare block sizes 2^9 bytes and 2^{10} bytes, and, in particular, configurations, printed in italic boldface font, for block size 2^9 bytes and heap size 240 blocks, and for block size 2^{10} bytes and heap size 120 blocks. These configurations are pairwise identical with respect to heap size and collected region size.

The differences in copying cost are small in some pairs, but significant in others, such as 30236 words copied for configuration $[9, 240, 108]$ vs. 44507 words copied for configuration

[10, 120, 54]. There are two reasons for the differences. First, blocks of different size cause different fragmentation at block boundaries. However, since blocks are already substantially larger than typical object sizes present in the trace, the effect of fragmentation should be small, and the effect of differences in fragmentation even smaller; moreover, larger blocks should suffer less from fragmentation than smaller blocks, whereas we see that the copying cost is lower for smaller blocks. The second reason, which applies here, is that positioning of the collection window in the FC-DOF scheme is constrained by block boundaries and is less flexible with larger blocks, and, as Section 5.4.5.2 has shown, window positioning is important for good performance of FC-DOF.

If we focus on pairs with similar copying cost, we note that larger blocks enjoy lower counts in columns "W.b. insert," "W.b. add," and "R.s. proc," which is to be expected. With larger blocks, a greater portion of pointer stores are block-local, hence filtered out. Note, however, that doubling the block size reduces the number of write-barrier and remembered set operations by only about 10% in these examples. The column "R.s. union" is not reduced by increasing block size since the number of external pointers into the collected area does not depend on its internal division.

For the 2GYF collector, Table 6.4, p. 310, again comparing the configurations for block size 2^9 bytes and heap size 240 blocks, and for block size 2^{10} bytes and heap size 120 blocks, we find that differences in copying cost are generally not large, and in some cases favor larger, whereas in other cases smaller blocks. The pointer management operation counts are not systematically affected by block size, which is to be expected, since the generational write barrier check ignores block boundaries, except to the extent that it is indirectly influenced by fragmentation.

6.1.3 Comparison between collectors

We compare the FC-DOF and the 2GYF collector with respect to copying and pointer management costs. Consider the benchmark StandardNonInteractive with a block size of 2^9 bytes

and heap size of 25 blocks, i.e., 3200 words (Table 6.2, p. 295). Among the configurations of the FC-DOF collector for this heap size, the lowest copying cost of 3902 words is achieved with a collected region size set to 4 blocks. We abbreviate this configuration as $[9,25,4]$. Among the configurations of the 2GYF collector for this heap size (Table 6.9, p. 335), the lowest copying cost of 15699 words is achieved with a younger generation set to 17 blocks, and older generation set to 8 blocks, abbreviated $[9,25,17,8]$. Thus the copying cost of the FC-DOF collector is significantly (4.02 times) lower than that of the 2GYF collector, which confirms, in the context of a block-based implementation, the observations we made in Sections 5.1 and 5.2.

The number of pointer management operations, however, is significantly higher for FC-DOF than for 2GYF. The number of non-filtered pointer stores is $\frac{688}{13} = 52.9$ times greater, and the number of processed remembered set entries is $\frac{615}{12} = 51.5$ times greater. It should come as no surprise that pointer management costs are higher in the FC-DOF scheme. The "R.s. union" column for FC-DOF indicates that the total number of pointers into the collected region (summed over all collections) is 392, whereas the corresponding number for 2GYF is just 12. Therefore, regardless of the efficiency of pointer filtering, when collected regions are chosen in the FC-DOF manner, the number of incoming pointers is high. The causes are in the small size of the region (and large size of the remainder), and the fact that the region visits all parts of the heap regularly, and some parts of the heap have many incoming pointers; we investigate pointer structure further in the following Section 6.2.

We can remark then on the efficiency of the FC-DOF filtering scheme of Section 3.2.2: out of 7251 pointer stores in StandardNonInteractive (Table 6.1), only 688 or 9.5% are inserted into remembered sets. This reduction in the number of pointer that are recorded is certainly not as good as 13 or 0.2% for the generational filtering of 2GYF. On the other hand, we noted that keeping a large number of pointers is a necessary price to pay in order to choose collected regions in a particular way. The true measure of the efficiency of the filtering scheme is therefore given by the ratio of the "R.s. proc" column and the "R.s. union" column: $\frac{615}{392} = 1.56$, thus 56% more pointers than is absolutely necessary are processed at garbage collection time.

We see that the copying cost is lower for the FC-DOF collector, and the pointer management cost is lower for the 2GYF collector. We must look at absolute numbers to determine which collector achieves a lower total cost. The difference in copying cost, in favor of FC-DOF, is 11797 words copied. The difference in pointer management cost, in favor of 2GYF, is 675 remembered set insertions (636 non-duplicate), and 603 processed entries at garbage collection time. Which of these is more expensive depends on the details of implementation. For the sake of a simple analysis, we subsume the different components of pointer management under the single appellation of *pointer processing cost*, which we associate with the highest operation count, that of the non-filtered pointer stores, thus erring conservatively in favor of the scheme with lower pointer management cost. If the cost of processing a pointer is greater than $\frac{11797}{675} = 17.5$ times the cost of copying a word at garbage collection time, then the 2GYF collector will have the advantage for benchmark StandardNonInteractive. (These break-even ratios are summarized for all examined configurations in Figures 6.1– 6.9, pp. 389–393 which we discuss below.)

If we are interested in *incremental* operation of the collector, then we should compare configurations that result in similar (and *large*) numbers of collector invocations. In this case, if the 2GYF collector is configured with the younger generation at 4 blocks, and the older generations at 21 blocks, then it will perform 418 collections, the same as the FC-DOF collector with the collection window of 4 blocks. The copying cost advantage of FC-DOF is now greater, 23510 words, but the pointer management advantage of 2GYF is only slightly smaller, 673 remembered set insertions (633 non-duplicate), and 600 processed entries at garbage collection time; the pointer/copy cost ratio would have to be over 34.9 for 2GYF to have the advantage.

Similar results obtain for the larger block size of 2^{10}: compare the configuration $[10, 13, 3]$ of FC-DOF with configuration $[10, 13, 7, 6]$ of 2GYF.

We turn our attention to benchmark HeapSim (Tables 6.3, p. 301 and 6.10, p. 343), at block size 2^{13} bytes and heap size 123 blocks, or 251904 words. The best configuration of FC-DOF is $[13, 123, 4]$, with copying cost 262984, with 4645 non-filtered pointer stores (of which 3731

non-duplicate), and 3297 processed entries at garbage collection time. The remembered set union total is 1628, thus the filtering efficiency is assessed at an overhead of 102% more processed pointers than is absolutely necessary. The best 2GYF configuration is $[13,123,41,82]$, with copying cost 341702, with 22 non-filtered pointer stores (of which 12 non-duplicate), and 12 processed entries at garbage collection time. The copying cost advantage of FC-DOF is 89798 words; the pointer/copy cost ratio would have to be over 19.4 for 2GYF to have the overall advantage. Similar results obtain for the larger block sizes of 2^{14} (compare the configuration $[14,62,3]$ of FC-DOF with configuration $[14,62,20,42]$ of 2GYF) and 2^{16} (compare $[16,16,4]$ with $[16,16,6,10]$).

In benchmark Richards (Tables 6.5, p. 322 and 6.12, p. 370), we consider the block size 2^{10} bytes, and heap size 20 blocks, or 5120 words. The best configuration of FC-DOF is $[10,20,8]$, with copying cost 56758, with 30270 non-filtered pointer stores (of which 29775 non-duplicate), and 29686 processed entries at garbage collection time. The remembered set union total is 11354, thus the filtering achieves an overhead of 161%. The best 2GYF configuration is $[10,20,11,9]$, with copying cost 631920, with 3754 non-filtered pointer stores (of which 1541 non-duplicate), and 1541 processed entries at garbage collection time. The copying cost advantage of FC-DOF is 575162, and its pointer management disadvantage is 28614 insertions (26021 for non-duplicates) and 28145 processed entries. The pointer/copy cost ratio would have to be over 20.1 for 2GYF to have the overall advantage. With twice as large blocks (configurations $[11,10,4]$ and $[11,10,6,4]$) the results are similar, and the pointer/copy cost ratio break-even point is 27.0.

The situation is somewhat different for Lambda-Fact5 (Tables 6.4, p. 310 and 6.11, p. 354). Recall that no collector worked much better than non-generational for this benchmark in object-level simulations of Section 5.1, and that differences among collectors were small. We now look at block size 2^9 bytes and heap size 90 blocks, or 11520 words. The best configuration of FC-DOF is $[9,90,67]$, with copying cost 134723, with 21778 non-filtered pointer stores (of which 21769 non-duplicate), and 21087 processed entries at garbage collection time. The

remembered set union total is 4365, which means that filtering is unusually inefficient here, at an overhead of 383%. The best 2GYF configuration is $[9, 90, 67, 23]$, with copying cost 158419, with 801 non-filtered pointer stores (of which 558 non-duplicate), and 557 processed entries at garbage collection time. The copying cost advantage of FC-DOF is 23696, but its disadvantage is 20977 insertions (21211 for non-duplicates) and 20530 processed entries. It is sufficient for the pointer/copy cost ratio to be over 1.12 for 2GYF to have the overall advantage.

Similarly, in Bloat-Bloat (Tables 6.7, p. 327 and 6.14, p. 376), we find that the copying cost difference between the collectors is very small, but the pointer management costs are noticeably higher for FC-DOF. For instance, with a block size of 2^{16}, and a heap size of 28 blocks, or 458752 words, the best configuration of FC-DOF is $[16, 28, 14]$, with copying cost 2308104 and 387199 non-filtered pointer stores, whereas the best configuration of 2GYF is $[16, 28, 13, 15]$, with copying cost 2498540 and 33304 non-filtered pointer stores. In this case it is sufficient for the pointer/copy cost ratio to be over 0.53 for 2GYF to have lower total cost.

In Toba (Tables 6.8, p. 331 and 6.15, p. 382), with 2^{16}-byte blocks and a heap size of 40 blocks, the difference in copying cost in favor of FC-DOF configuration $[16, 40, 25]$ is 756188 words, and the difference in pointer cost in favor of 2GYF configuration $[16, 40, 23, 17]$ is 288379 operations, giving a pointer/copy cost ratio threshold of 2.62.

Benchmark JavaBYTEmark stands out (Tables 6.6, p. 326 and 6.13, p. 375). We look at block size 2^{18} bytes and a heap size of 6 blocks, or 393216 words. One of the (tied) best configurations of FC-DOF is $[18, 6, 3]$, with copying cost 17634 words, with 23 non-filtered pointer stores (out of 49061 pointer stores), 19 non-duplicate, and 19 processed entries at garbage collection time. The best 2GYF configuration is $[18, 6, 5, 1]$, with copying cost 37842 words, with 135 non-filtered pointer stores (of which 102 non-duplicate), and 16 processed entries at garbage collection time. Here both collectors have negligible pointer management costs, but FC-DOF is better, by more than a factor of 2, with respect to copying cost.

A summary of the break-even ratios of pointer-operation cost to word-copying cost is presented in Figures 6.1–6.11, pp. 389–394 (at the end of this chapter), for all simulated heap

sizes, including the exemplars discussed above. In these graphs, the horizontal axis indicates the heap size (in words), and the vertical axis indicates the break-even ratio, shown on a logarithmic scale. Each graph contains several data lines, one for each block size. For example, Figure 6.1 has three lines, for block sizes 2^9, 2^{10}, and 2^{11} words. If in an implementation the ratio of the cost of a pointer operation to the per-word cost of copying is above the point in the graph, then 2GYF has a lower cost overall than FC-DOF.

6.1.4 Additional observations

In addition to the comparison between FC-DOF and 2GYF, we can observe a trade-off between copying cost and pointer-maintenance cost in the configurations of FC-DOF itself. Consider for instance the configurations $[16, 28, *]$ of benchmark Bloat-Bloat. As the size of collected region is increased from 11 to 26 blocks, the copying cost first briefly falls from $2.6 \cdot 10^6$ at 11 blocks to the minimum of $2.3 \cdot 10^6$ at 13 blocks (the configuration we compared against 2GYF above), then rises to $5.4 \cdot 10^6$ at 24 blocks, and briefly falls to $5.2 \cdot 10^6$ at 26 blocks. Although the copying cost is not strictly monotone increasing, it shows a clear increasing trend. At the same time, the "R.s. union" column shows a decreasing trend, from 106683 entries in the remembered set union with collected region of 11 blocks, down to 29426 with 26 blocks. The actual processing costs in the "R.s. proc" column are also nearly monotone decreasing.

An examination of all the tabulated results for the FC-DOF collector reveals that there are remarkably few duplicate entries: the values in the "W.b. add" column are close to those in the "W.b. insert" column. Therefore, it is not essential to eliminate duplicates early in pointer management. A simple sequential store buffer representation of the remembered set, which does not remove duplicates, may be adequate.

With the single generational remembered set of the 2GYF collector, the number of duplicates is significant: the values in the "W.b. add" column are typically well below those in the "W.b. insert" column. When the proportion of duplicate entries is large, it is worth eliminating

them early and cheaply, e.g., by using a card-marking write barrier, with cards flushed into sets without duplicates.

Since the proportion of pointer stores retained is higher in the FC-DOF collector than in the 2GYF collector, the amount of auxiliary space needed for the remembered sets is higher, which raises the concern about the *total* memory usage of the collector. It turns out, however, that the space needed for remembered sets is typically below 2% of heap size. In particular, assuming that a remembered set entry uses one word, the total size of remembered sets for all heap blocks is 0.62% of total heap size for StandardNonInteractive (in the configuration discussed above), 0.49% for Richards, 1.38% for Bloat-Bloat, and 1.02% for Toba. Therefore, the space overhead of pointer maintenance in FC-DOF is low.

The measured values for individual copying and pointer-tracking operations (Section 3.2.5) permit a more detailed estimation of the total cost of collection. However, our trace-based simulation does not simulate stack contents, and therefore, while its copying counts are accurate, it cannot model the pointer-scanning counts: the number of scanned pointers in to-space that do not result in object copying depends on the contents of the stack. We can establish lower and upper limits, however. The lower limit corresponds to approximately one duplicate pointer per object, that one being the pointer to the class object. The upper limit corresponds to all words being duplicate pointers. We assume individual operation costs as in Section 3.2.5, and, for a given heap size, we allow each collector to assume its best configuration with respect to the total cost estimate. For the heap sizes as in the examples discussed above, the lower and upper bounds for the ratios of total processor cycles spent on garbage collection by 2GYF and by DOF are as follows: for benchmark StandardNonInteractive, between 2.66 and 3.28; for benchmark Richards, between 3.84 and 5.70; for benchmark Lambda-Fact5, between 0.98 and 1.04; for benchmark JavaBYTEmark, between 2.16 and 2.48; for benchmark Toba, between 0.98 and 1.08; for benchmark Bloat-Bloat, between 0.94 and 0.98. Therefore, pointer management costs do not significantly alter the qualitative performance relationship between the two collectors that we established when considering the amounts copied in Chapter 5: DOF

remains significantly better than 2GYF on one set of benchmarks, while not significantly worse than 2GYF on the remaining benchmarks.

6.2 Methods for examining the directions of pointers in the heap

An evaluation of the cost of remembered-set maintenance provides us with raw numbers, such as the number of executed write-barrier checks, the number of processed remembered-set entries, and an estimate of the time penalty of these operations. Upon seeing these numbers, we can assess the effect of pointer tracking on different collectors, but we are at a loss about the origins of the effect. Just as it is necessary to recognize where (in which region of the heap) the high copying cost was incurred, it is necessary to recognize *where* in the heap the pointer-tracking costs arise, if we are to understand and remedy the situation. Our purpose is to establish quantitative measurements where the literature so far provides speculative statements.

6.2.1 Pointer stores in the ideal heap

We begin with an examination of pointer store directions in an absolute sense, without reference to a specific collection algorithm, assuming instead that the heap is perfectly collected, as we did for the heap profiles in Section 5.4.3. For each non-null pointer store, we note the heap position of both the pointer source and the pointer target. Recall that the heap position of an object is expressed as the distance from the young end of the heap, i.e., the amount of data that was allocated since that object was allocated and is still live. We define pointer *distance* as the difference between the heap position of the pointer target and the heap position of the pointer source. Hence, the distance is positive for younger-to-older pointers, and negative for older-to-younger pointers. Aggregating over all stores, the distribution of the positions is shown in Figures 6.12–6.25, pp. 395–408 (at the end of this chapter). Each figure contains three plots: (a) a histogram of the distribution of heap positions of pointer sources; (b) a histogram of the distribution of heap positions of pointer targets; and (c) a cumulative distribution graph for pointer distances and directions.

The pointer source histograms for all programs have a peak in the low positions, the youngest objects. A majority of pointer stores are into the most recently allocated objects. We emphasize that the histogram excludes null pointer stores, therefore the default initializations of pointer fields to the null pointer do not skew the distribution. Only the actual initializations by assignment are reflected in the histogram. The pointer *target* distributions also exhibit sharp peaks for the youngest objects, and indeed the fact that pointer distances are very short means that the source and target distributions must be similar. Thus a majority of pointers are from one object in the youngest part of the heap to another.

We now understand that the generational write barrier works well because for most pointer stores, both the source and the target are in the youngest generation, and thus the store need not be recorded. The putative explanation, that older-to-younger pointers are rare relative to younger-to-older pointers, is neither true (as the pointer distances graphs show, both directions are common), nor relevant.

Two programs with exceptional behavior are Swim and Tomcatv; they have secondary peaks of the pointer source distribution among the oldest objects. Both of these programs use a common implementation of floating-point matrices. A floating-point value in Smalltalk is not represented as an immediate register value, because the necessary tag bit(s) would both limit precision and require expensive conversions to the hardware floating-point format. Instead, a level of indirection is used, and each floating-point value is allocated in the heap. Computation creates new floating-point objects and updates the elements of a matrix to point to them. Since the matrix itself is allocated early in program execution, computation produces a stream of old-to-new pointer stores This peculiarity of the Smalltalk floating-point representation, and similar situations with frequently updated data structures with *boxed* representations in general and their interaction with the write barrier, have been noted before [Wilson, 1990; Chambers, 1992; Wilson, 1992] as a potential problem for the generational write barrier.

6.2.2 Pointer stores and remembered sets in age-based collectors

We now examine the pointer distributions that arise as a result of the execution of particular collection algorithms. Our frame of reference is an age-ordered heap, divided into blocks of equal size. The heap position of the youngest block (i.e., the current allocation block) is numbered 0, and older blocks are given successive numbers. We are interested in the distribution of pointer-tracking events by heap position. In other words, we are interested, having observed the positional distribution with an ideally collected heap, in any bias that the actual collection scheme introduces.

The resulting pointer source and target distributions are shown in plots (a)–(d) of Figures 6.26–6.31, pp. 409–414, for the benchmarks and their configurations discussed in the preceding Section 6.1.3. Plots (a) and (c) on the left reflect all non-null pointer stores, whereas plots (b) and (d) on the right reflect only those stores not eliminated by filtering, i.e., those inserted into remembered sets. Plots (a) and (b) show the histogram of positions of the pointer source, whereas plots (c) and (d) show the histogram of positions of the pointer target.

Additionally, the bottom plots (e) of Figures 6.26–6.31 show the positional distribution of the remembered set entries chosen for processing at garbage collection time.

The plots (a) and (c) show the same patterns as the corresponding plots (a) and (b) for the perfectly collected heap in the preceding section. Therefore, the FC-DOF collector, owing to its regular full sweeps, does not maintain large quantities of uncollected ("tenured") garbage, which, if present, would visibly distort the distribution relative to the perfectly collected heap.

Of greater interest is the distribution of heap position among the *non-filtered* pointer stores, in plots (b) and (d). First note that the absolute numbers are much smaller, since filtering eliminates most pointer stores.

A majority of the non-filtered stores still have their source in the youngest block (position 0). The non-filtered targets in the youngest block are few, because of the block-local filtering. However, there are many targets tailing off from block 1 towards older blocks—the directional filter could not eliminate the pointers from block 0 into these older blocks. In Lambda-Fact5

there is also a large number of pointers with source in block 0 and target among the very oldest objects.

When a filter cannot eliminate a pointer store, it inserts it into the remembered set of the target block. Thus, most pointers are inserted into the remembered sets of blocks at low positions (but not position 0). However, some time elapses between the pointer store and the time when the target block becomes part of the collected region of a collection, and during that time the block ages and moves toward higher heap positions. Therefore, in the distribution of heap positions of *processed* remembered set entries, the peak is in the middle or higher (older) regions. In Lambda-Fact5, for instance, just the oldest of the 90 blocks accounts for 30% of all processed remembered set entries (Figure 6.29(e), p. 412). Recall that the oldest blocks contain permanent data (Figure 5.271, p. 258), hence collections immediately following the resetting of the window not only incur a high copying cost, but also a high pointer processing cost.

Benchmark JavaBYTEmark is an exception: the filtering is so successful that very few pointers remain non-filtered, and, with their number so small, it is not warranted to discuss their positional distribution.

6.3 Method for evaluating the collection start-up cost

In addition to the copying cost of collection, which is directly related to the efficiency of the collector in finding low-survival regions, and the remembered-set maintenance cost, which is related to the ability of the collector to approximate the structure of the uncollected region safely and cheaply, there are other costs that are incurred on every collection.

First, there is a direct overhead of switching system activity from the mutator to the collector. This overhead depends on the implementation details. In some implementations, the collection is triggered by a page fault on accessing a protected page past the end of the available nursery space, or it may involve saving architectural state because the mutator is written in a different language from the garbage collector itself, and in these cases the start-up may

be costly. On the other hand, this direct overhead is minimal in virtual machine implementations. The change of program focus from the mutator to the collector also has an adverse effect on reference locality—the performance of the instruction cache, and possibly the data cache, degrades.

Second, each collection requires establishing the global roots. These are found in the registers (machine or virtual) and in the stack (if the implementation uses an explicit stack). Whether this task is a large fraction of total garbage collection cost depends on the implementation: in the case of an explicit stack, has the implementation provided stack maps in a form that permits efficient stack scanning [Diwan *et al.*, 1992]?[1]

The cost of stack scanning is not directly dependent of the garbage collection algorithm that is subsequently employed. However, the cost of one stack scan depends on the stack state (how many activation records there are on the stack), hence it depends on the moment at which it is examined. Since different collector algorithms result in different moments of collector invocation, there is an indirect dependence of total scanning cost on collection algorithm, beyond the mere number of invocations, but with many invocations spread over the execution, with somewhat asynchronous points of collection, this additional dependence is probably very weak.

In summary, there is a certain fixed cost to be paid for each collector invocation. If we are primarily concerned with the total running time of the program, then we must be careful in the choice of the garbage collection algorithm lest it cause too many collector invocations. For many programs, we found that the lowest copying costs are obtained with smaller collected regions or smaller nurseries, and consequently with larger numbers of collector invocations. Clearly, when some rather large number is reached [Stefanović and Moss, 1994], the invocation costs will dominate.

---

[1] In the case of a stack hidden within the heap, stack scanning is implicitly accomplished during the Cheney scan phase of garbage collection, so it is difficult to isolate the stack scanning cost.

If, on the other hand, the primary consideration is that of minimizing pause times, then the invocation cost represents a fixed component that cannot be avoided. Since this cost is independent of the collection algorithm, except as mentioned above, it is still appropriate to choose an algorithm that minimizes the other costs.

6.3.1 Results

The invocation cost is shown in Figures 6.32–6.135, pp. 415–459. The vertical axis shows the number of collector invocations *relative* to the non-generational collector. (This permits us to use the same scale for all plots for a given benchmark.) As before, the horizontal axis in the FC plots gives the size of the collected region expressed as the fraction g of heap size. In the GYF plots, the horizontal axis gives the size of the nursery as a fraction of heap size.

A very regular pattern emerges, for all benchmarks, and all heap sizes: when the size of the collected region (or nursery size) is close to the full heap size, the behavior is non-generational and the relative invocation count is close to 1; but as the size of the collected region decreases, the invocation count increases. This result is intuitively clear: the amount of garbage found by a collection cannot be larger than the size of the collected region, thus the number of collector invocations must rise as the reciprocal of that size, if we ignore for a moment the influence of that size on the proportion of survivors.

6.4 Summary

We have shown that pointer-maintenance costs in a generational collector are very low, confirming past research. The analysis of pointer stores reveals that the explanation lies in the location of stored pointers (in recently allocated data) and not in the temporal direction of pointers (younger-to-older or older-to-younger).

The FC-DOF collector, because it collects smaller regions in all parts of the heap, incurs a considerably higher pointer maintenance cost, both in the higher number of pointer stores that must be recorded at run time (even after efficient filtering), and in the high number of incoming

pointers processed at garbage collection time. Our trade-off analysis suggests that the copying cost advantage of DOF outweighs the pointer cost disadvantage for several tested programs, but the final verdict must await a full implementation.

Let us note, however, that the focus of our study on the application of collectors to the entire heap precluded an investigation of the space of older (mature) objects only, in which the distributions of pointer stores as well as the distribution of lifetimes is less favorable to the generational approach (to the extent that this can be plausibly inferred from observations of relatively longer-lived objects in our programs). Moreover, it can be argued, pending further measurements, that, with remembered set costs having already been absorbed in the mature object space [Hudson and Moss, 1992], deferred older-first becomes a collection *policy* worth exploring. It is a different policy from the *train* algorithm [Hudson and Moss, 1992; Seligmann and Grarup, 1995]; in particular, it does not guarantee reclamation of arbitrary cycles. On the other hand, the train algorithm leaves certain promotion decisions for objects moved out of a train underspecified; whereas locality (for the purpose of exploiting *key object opportunism* [Hayes, 1991]) is suggested as a criterion for making these decisions (thus: moving an object close to the object that keeps it live by pointing to it), age is a permissible criterion as well.

CHAPTER 7

CONCLUDING REMARKS

In this study, we have explored a heretofore neglected alternative to generational garbage collection and found it to be competitive with generational algorithms, and in many cases superior to them. We introduced a simple new algorithm, called deferred older-first, within the classification of age-based algorithms. We described an efficient implementation of the new algorithm, its heap organization, copying mechanisms, and pointer-maintenance mechanisms (Chapter 3). We demonstrated, in a comparative trace-based simulation study, that the new algorithm achieves a significantly lower copying cost than generational collection on many programs, sometimes as much as 11 times lower (Chapter 5). We showed that, even though the pointer-maintenance cost of the new algorithm is usually higher than that of generational collection, the total cost is nevertheless lower on many programs, sometimes as much as 4 times (Chapter 6). These results were unexpected in light of the prior understanding of generational collector performance, which suggested that collecting among the youngest data achieves the best performance.

Using profiling of an age-ordered heap, our investigation provides insight into the copying performance of the new algorithm, and shows how it genuinely concentrates effort on those object ages, neither the youngest nor the oldest in the heap, which result in the lowest copying cost. Our new algorithm is very simple, and non-adaptive, yet its performance is good. While much work has been devoted to the design of adaptive generational algorithms, adaptive versions of our alternative, or indeed, other alternatives, are unexplored, but, according to our results, promising. Thus the field of garbage collection, even in the simplest setting of stop-and-copy uniprocessor algorithms, is reopened for study.

In our examination of the pointer-maintenance structures to support the demands of new algorithms, we found that precepts for the design of pointer maintenance from existing studies of generational collection do not carry over to alternative algorithms (for instance, the number of duplicate remembered set insertions is much greater in generational collection), and thus pointer maintenance design is also open for further study. Furthermore, the investigation of the positional distribution of pointers dispells the oft-cited notion that younger-to-older pointers dominate even in object-oriented languages.

This work has exposed the facts about the performance of copying garbage collection algorithms, the factors affecting it, and the limits of its possible improvement. However, the settings in which the experimental results were obtained were necessarily limited, and other settings remain to be explored.

We used trace-based simulation, albeit in conjunction with a prototype implementation of the collectors. However, traces do not capture stack processing costs nor the interactions between the collector and the mutator. A desirable follow-up study is to integrate the several collectors we described with a running mutator system, such as a Java virtual machine. This integration will permit the verification of the design we outlined for implementation, the validation of the cost models we assumed (Chapter 3), the measurement of memory locality effects, and the final verdict in the form of absolute timing of different algorithms.

In this study, we eschewed analytical modelling of garbage collection costs. Modelling the actions of a collector presupposes the availability of analytical models for the behavior of the mutator. Whereas some models have been attempted for object lifetimes, with unclear utility, models for pointer structure are entirely unexplored. The success of the deferred older-first collector as an approximation of the ideal queue collector (Chapter 1), the heap profiles (Chapter 5), and the pointer distributions (Chapter 6) indicate a high degree of spatio-temporal correlation of object lifetimes and of pointer structure, suggesting that first-order statistical models will be inadequate.

Our investigation focused on the application of collectors to the entire heap, from the most recently allocated objects to the oldest ones. As we discovered in the study of demise positions as well as of pointer directions, and entirely in accordance with intuitive expectations, an advantage is possible in large and long-running systems if an *a priori* division is imposed on the heap, in which the most recently allocated data are managed separately to lower the pointer maintenance overhead for stores into new objects, the oldest data are identified as permanent (by programmer declaration, or adaptively) to exclude them from consideration entirely, and the middle portion, representing an active mature space, is managed by a deferred-older-first algorithm. Indeed, this observation can be seen as the basis for defining policies on top of the mechanisms described for the Mature Object Space and its *train* algorithm [Hudson and Moss, 1992; Seligmann and Grarup, 1995].

The evaluation of different algorithms applied to a mature space could, in principle, proceed as in this study. The trace of mature space objects can be obtained either as the sequence of objects promoted out of a concrete younger-space collector, or, more abstractly, as the subsequence of objects with lifetimes above a fixed threshold extracted from a full sequence of allocated objects. Since the volume of objects presented to the mature space collector is, by design, much smaller than the total volume of allocation, then, in order for the mature space collector to be exercised sufficiently (Section 4.2.2.2) the total allocation must be considerably larger. We believe that it will prove infeasible to obtain accurate traces as for this study, and that direct implementation and measurement will be especially needed for the mature space.
