March 9, 1994

An $O(n \ \log^3 n)$ Algorithm for the Real Root and Symmetric Tridiagonal Eigenvalue Problems

John H. Reif Department of Computer Science Duke University [‡]

May 20, 1994

Abstract

Given a univariate complex polynomial f(x) of degree n with rational coefficients expressed as a ratio of two integers $< 2^m$, the root problem is to find all the roots of f(x) up to specified precision $2^{-\mu}$. In this paper we assume the arithmetic model for computation. We give an algorithm for the real root problem: where all the roots of the polynomial are real. Our real root algorithm has time cost of $O(n \log^2 n (\log n + \log b))$, where $b = m + \mu$. Our arithmetic time cost is thus $O(n \log^3 n)$ even in the case of high precision $b \leq n^{O(1)}$. This is within a small polylog factor of optimality, thus (perhaps surprisingly) upper bounding the arithmetic complexity of the real root problem to nearly the same as basic arithmetic operations on polynomials.

The symmetric tridiagonal problem is given a $n \times n$ symmetric tridiagona matrix, with 3n nonzero rational entries each expressed as a ratio of two integers $< 2^m$, find all the eigenvalues up to specified precision $2^{-\mu}$. Using known efficient reductions from the symmetric tridiagonal eigenvalue problem to the real root problem, we also get an $O(n \log^2 n (\log n + \log b))$ arithmetic time bound for the symmetric tridiagonal eigenvalue problem.

We require only $\pi = O(n(b+n))$ bits of precision to carry out our computations. The Boolean complexity of our algorithms are a multiplicative factor of $M(\pi)$ more, where $M(\pi) = O(\pi(\log \pi) \log \log \pi)$ is the bit complexity for multiplication of integers of length π .

1 Introduction

1.1 Definition of the Root Finding Problem

Let the *log-precision* of a rational number x be m if x can be expressed as a ratio of two integers $< 2^m$. Let f(x) be an univariate polynomial

$$f(x) = \sum_{i=0}^{n} c_i x^i$$

of degree n with each coefficient c_i given within log-precision m. The root finding problem is: given b, approximate all the roots of f(x) within given log-precision μ , where $b = m + \mu$. The real root finding problem is the root finding problem given a polynomial with all real roots.

For our model of computation, we assume the *algebraic random access machine (RAM)* where each arithmetic or logical operation such as addition, sub-traction, multiplication, division, and comparison can be done in one step. The *time complexity* bound of an algorithm is defined to be the number of these steps of the algebraic RAM. We define *space complexity* as the number of memory locations used, where we can store a single rational number in each memory location.

1.2 Application of the Real Root Problem: the Symmetric Eigenvalue Problem

The real root problem has many applications, and one of the most important of these is the *symmetric eigenvalue problem*: given a symmetric matrix, find all the eigenvalues; which are all real in this case. The real eigenvalues are used for many engineering and scientific applications, including vibration analysis in structures, stability analysis, etc. The eigenvalues are the roots of the characteristic polynomial of the matrix. Many large matrices occurring in practice have a special structure which allow the characteristic polynomial to be computed quickly, for example

- 1. dense structured matrices (e.g. Toeplitz and bounded displacement rank matrices), with $O(n^2 \log n \log \log n)$ algorithms (see Pan [Pa 90]),
- 2. sparse with $O(n^2 \log^2 n)$ algorithms (see Canny, Kaltofen and Laksman [CKL 89])
- 3. tridiagonal or banded.

The symmetric tridiagonal matrix eigenvalue problem is the problem of finding all the eigenvalues of an $n \times n$ symmetric tridiagonal matrix

$$A = \begin{bmatrix} b_1 & a_2 & 0 & 0 & \dots & 0 & 0 & 0 \\ a_2 & b_2 & a_3 & 0 & \dots & 0 & 0 & 0 \\ 0 & a_3 & b_3 & a_4 & \dots & 0 & 0 & 0 \\ \vdots & & \ddots & \ddots & & & & \\ & & & \ddots & \ddots & & & \\ 0 & & & & & \ddots & \ddots & & \\ 0 & & & & & & 0 & a_n & b_n \end{bmatrix}$$

The real roots problem has an efficient reduction to and from the symmetric tridiagonal matrix eigenvalue problem, which has been attributed to Hald [H 76] and described in [KM 86, BP 91, BP 92, BG 92] and also by JáJá [J 92], p428, homework 8.37. (This relationship is well-known among numerical analysts and they are encountered in different computational problems as inverse eigenvalue problems, orthogonal polynomials, Sturm sequences, three-term recurrences, Euclidean scheme and Lanczos algorithm.) This reduction from the symmetric tridiagonal matrix eigenvalue problem for the above matrix A to the real roots problem requires us to compute the characteristic polynomial det $(\lambda I - A)$. We sketch here this efficient reduction, with arithmetic cost $O(n \log^2 n)$. For each $i = 1, \ldots, n$ let $p_i(\lambda) = \det (\lambda I - A^{(i)})$, where $A^{(i)}$ is the $i \times i$ submatrix consisting of the first i rows and the first i columns. Note that $p_0(\lambda) = 1$, $p_1(\lambda) = \lambda - b_1$, and $p_i(\lambda) = (\lambda - b_i)p_{i-1}(\lambda) - a_i^2 p_{i-2}(\lambda)$. This recurrence equation (see JáJá [J 92]) can be solved for $p_n(\lambda) = \det (\lambda I - A)$ within arithmetic work $O(n \log^2 n)$, or in parallel time $O(\log^2 n)$ using $O(n \log n)$ processors.

(The reverse reduction of the polynomial root-finding problem for a polynomial f(x) to the symmetric tridiagonal matrix eigenvalue problem, performed by means of the Euclidean remainder scheme, can be found in Hald [H 76]. This reverse reduction is used also in [BP 91, BP 92, BG 92], and shown to have Boolean cost $O(M(n)M(nm)\log n)$. The arithmetic cost for this reduction is easily be seen to be $O(n \log^2 n)$. The Euclidean scheme can be applied to f(x)and f'(x) or equivalently, to f(x) and g(x) where $f'(x_i)g(x_i) > 0$, $f(x_i) = 0$. The computation of this reduction can be performed by means of the "quotienttree" procedure of [BT 90] (sect. 8.1), in fact the 2×2 matrices s_i yield all the quotients and the leading coefficients of the remainders, i.e., the entries of the tridiagonal. Recovering the coefficients of the polynomial, given the entries of the matrix is described in [BP 91, BP 92, BG 92] (comments after algorithm 3.1.) and this problem can be equivalently solved by means of the technique of [KM 86].)

1.3 History of the Root Problem and Previous Work in the Arithmetic Model

The problem of root finding is a classical problem, dating at least to the era of the Greeks, with modern applications in many areas of science and engineering.

The fundamental theorem of algebra states that every polynomial of degree n over the field of complex numbers has n roots. The first rigorous constructive proof of the fundamental theorem of algebra, which can be viewed as an algorithm for the root problem with a correctness proof, is due to Lehmer in 1961. Gargantini and Henrici [GH 72] gave an $O(n^3b)$ arithmetic time algorithm. The seminal work of Schönhage [S 82] gave a description and analysis of many techniques for root finding, with detailed precision analysis in the bit complexity model. Since then, there has been some progress toward precisely bounding the arithmetic complexity of the root problem. Let $b = m + \mu$. Although the algorithm of Schönhage [S 82] was not analyzed in the arithmetic model, it can be seen to require $O(n^2 \log^{O(1)}(bn))$ arithmetic operations, which is $O(n^2 \log^{O(1)} n)$ in the case of precision $b \leq n^{O(1)}$. Renegar [R 87] gave a $O((n + \log b)n^2 \log n)$ arithmetic time algorithm, which is $O(n^3 \log n)$ in the case of precision $b < n^{O(1)}$, but is an improvement in the case of extremely large (super-polynomial) precision. Pan [P 87] gave an $O(n^2 \log b \log n)$ arithmetic time algorithm based in part on the methods of Schönhage, which is the best known bound for the sequential arithmetic complexity of the root problem. Pan [P 89] recently investigated the complexity of the real root problem in the arithmetic model, achieving processor bounds n^2 with $O(\log^2 n(\log^2 n + \log b))$ parallel time, but no improvement on his previous sequential bounds for the general root problem. Ben-Or and Tiwari [BT 90] investigated the bit complexity of the real root problem. Bini and Pan [BP 91, BP 92] recently developed an efficient algorithm (which they view as a matrix reformulation of the Ben-Or and Tiwari [BT 90] algorithm) for the symmetric tridiagonal matrix eigenvalue problem, which has arithemetic time cost $O(n \log^2 n \log^2 b)$. Using the known efficient reduction from the real root problem to the symmetric tridiagonal matrix eigenvalue problem describe in Subsection 1.2, their resulting real root algorithm has the same arithemetic time cost of $O(n \log^2 n \log^2 b)$, thus has time bound $O(n \log^4 n)$ in the case of precision $b \leq n^{O(1)}$. In contrast, our real root algorithm has arithmetic time cost of $O(n \log^2 n (\log n + \log b))$ and thus $O(n \log^3 n)$ in the case of precision $b \le n^{O(1)}$. See the Conclusion (section 13) of our paper for a discussion of the Boolean complexity of these algorithms.

1.4 Techniques used to Solve Root Problems

The following technical definitions will be of use in the discussion of root finding techniques below. For any fixed $\epsilon, 0 < \epsilon < 1/2$, an interval [s, s'] on the real line is an ϵ -splitting interval for the roots of f(x) if the interval [s, s'] contains

exactly *i* roots of f(x), for some *i*, where

$$\epsilon n \leq i \leq (1 - \epsilon)n.$$

(See Figure 1). The ϵ -splitting is *balanced* if ϵ is a constant independent of n. For any real $\alpha, \sigma, \delta > 0$, an interval

$$I = [\alpha - \delta, \alpha + \delta]$$

is σ -isolated with respect to the roots of f(x) if the larger interval

$$[\alpha - (1+\sigma)\delta, \alpha + (1+\sigma)\delta]$$

has no further roots of f(x) other than those contained already in I (See Figure 2). An interval is well isolated if it is σ -isolated, for $\sigma \geq \Omega(1/n)$ and is highly isolated if it is σ -isolated, for $\sigma \geq \Omega(1)$.

The techniques used in root finding algorithms (also see the recent text of Mignotte [M 92] for an excellent survey) are:

- 1. Sturm defined in 1829 a sequence of polynomials known as the Sturm sequence, which can be used for counting the number of roots on interval of the real line. In 1988, Ben-Or, Feig, Kozen and Tiwari [BFK 86] showed that given a polynomial of all n real roots, a Sturm sequence can be used to find a point on the real line that gives a balanced splitting of the roots into sets whose size is a constant fraction of n. In particular, they found a 1/4-splitting interval. This gave them a divide and conquer NC algorithm for the real root problem. Ben-Or and Tiwari [BT 90] gave an efficient implementation of this parallel algorithm for the real root problem in the bit complexity model. Subsequently, Neff [N 90] generalized this technique to find all the roots in NC in the case where the polynomial has complex roots.
- 2. Geometric techniques for search and exclusion on the complex plane were developed by Lehmer and Weyl (see [H 70]) and require analytic mappings (such as translation, deflation and inversion) on the variable of a polynomial which can be efficiently computed by reduction to convolution and thus FFT.
- A method due to Turin in 1968 [T 68, T 75, T 84] can be used to determine approximations to the magnitudes of all the roots of a polynomial. Schönhage [S 82] gave an efficient implementation of Turin's method.
- 4. Schönhage [S 82] developed efficient techniques based on the method of Turin for finding a well isolated interval (which, however, may not be a nontrivial splitting interval). Pan [P 89] gave an algorithm, requiring at least quadratic time, for finding a well isolated, balanced splitting interval.

- 5. An algorithm known as Graeff's Method,(see [H 70]) but which is actually due to Dandelin, 1826, can be used to separate the roots by repeated powering while still maintaining the same degree. Graeff's Method can be used to find a highly isolated splitting interval. After the roots are determined in the powered polynomial then the roots must be extracted for the original polynomial, requiring 2n root proximity tests.
- 6. Turin's method [T 68, T 75, T 84] can also be used to determine if a given point is in the proximity of a root. This method requires at least quadratic time to determine which of 2n points are in the proximity of n roots.
- 7. It was shown in the early 1800s (also see Henrici [H 74]) that the Cauchy contour integration formula gives the *power sums* of the roots within the integration contour. Schönhage [S 82] showed that if the roots are highly isolated and thus sufficiently far from the contour, then the contour integration can be done by reduction to DFT. This gives a relatively low precision approximation to the power sums. (Also, even if the roots are not sufficiently far from the contour, the contour integration can still be done within appropriate accuracy by careful choice of the discrete points used to approximate the contour integral; see Ben-Or, Feig, Kozen and Tiwari [BFK 86], and Neff [N 90].)
- 8. The coefficients of a factored polynomial can be efficiently determined from the power sums by use of a triangular Toeplitz linear system known as *Newton's identities*. Thus a polynomial can be split into two factor polynomials by Cauchy contour integration followed by solution of a triangular Toeplitz system.
- 9. Newton's iteration method for finding a root within high accuracy from an approximation with low accuracy was analyzed in the average case in the works of Smale [S 81, S 85, S 86] and Shube, Smale [SS 85, SS 86], and can be efficiently applied to improve the precision of approximations to all roots by use of multipoint evaluation. Also, Newton's iteration method was used by Schönhage [S 82] to exponentially improve the accuracy of polynomial splitting.

1.5 Organization of this paper

Section 1, the introduction, defines the root finding problem, discusses related history and previous work, looks at application to the symmetric eigenvalue problem, and examines techniques used to solve root problems. Section 2 summarizes our real root algorithm. Section 3 presents some preliminary results for arithmetic on polynomials, translation, deflation, and inversion operations on polynomials, reduction to simplified root finding problems, bounds on roots (root separation), and bounded precision polynomial approximation. Section 4 deals with Sturm sequences and root isolation, while sections 5 and 6 deal with approximating the magnitudes of all the roots and finding a well-isolated ϵ -splitting interval, respectively. Section 7 discusses obtaining a highly isolated interval by polynomial powering, while section 8 discusses FFT approximations to contour integrals. Section 9 describes polynomial splitting using the Newton identities. Section 10 deals with high accuracy calculations using Newton iteration, specifically polynomial splitting and improving the accuracy of root approximations. Section 11 discusses fast root proximity verification. Section 12 describes an application of the real root problem: the symmetric eigenvalue problem in sparse and structured matrices. Finally, sections 13 and 14 are the conclusion and acknowledgments.

2 Summary of Our Real Root Algorithm

We will use all the above techniques for our real root finding algorithm.

In the following, we assume the input polynomial has degree n, with each coefficient given within log-precision m, and we wish to approximate all the roots within given log-precision μ .

Our main result is

Theorem 2.1 There is an algorithm for the real root problem which has arithmetic time cost $O(n \log^2 n(\log n + \log b))$, where $b = m + \mu$, using arithmetic steps with log-precision

$$\pi = O(n(\mu + m + n)).$$

Proof:

Will use all the above techniques for our Real Root Algorithm. Because of the large number of details of our Real Root Algorithm, will present it in three stages of increasing detail and complexity.

A Naive Version of our Real Root Algorithm is summarized below:

INPUT A monic polynomial f(x) with degree n and log-precision m.

OUTPUT A set S of n rationals approximating the roots of f(x) within log-precision μ .

Goal: Split polynomial $f(x) = f_1(x)f_2(x)$ into factors $f_1(x), f_2(x)$ where

$$deg(f_1(x)) \ge \epsilon n$$
,

$$deg(f_2(x)) \le (1-\epsilon)n,$$

for constant $\epsilon, 0<\epsilon<1$

We will use log-precision $\pi = O(n(\mu + m + n)).$

1. Get high accuracy approximation to factors $f_1(x), f_2(x)$ with error $\leq 2^{-\pi}$.

2. recursively factor $f_1(x)f_2(x)$, with error $\leq 2^{-\pi}$.

In fact we do not actually split f(x), and instead recursively split a related polynomial $\hat{f}(y)$, and then recover the roots of f(x) from the roots of $\hat{f}(y)$. We outline our slightly more detailed our real root algorithm below.

Outline of Our Real Root Algorithm

INPUT A monic polynomial f(x) with degree *n* and log-precision *m*.

OUTPUT A set S of n rationals approximating the roots of f(x) within log-precision μ .

We will use log-precision $\pi = O(n(\mu + m + n)).$

- 1. Eliminate any multiple zeros.
- 2. Construct from f(x) a poly $\hat{f}(y)$ of deg n with highly isolated balanced splitting interval \hat{I} .
- 3. Get high accuracy approximation to factors $\hat{f}_1(y)$, $\hat{f}_2(y)$ of $\hat{f}(y) = \hat{f}_1(y)\hat{f}_2(y)$ with $deg(\hat{f}_1(y))$, $deg(\hat{f}_2(y))$ both bounded by n5/6.
- 4. Recursively approximate factor $\hat{f}_1(y), \hat{f}_2(y)$, giving set S' of n high accuracy approx roots of $\hat{f}(y)$.
- 5. From S', using our fast root proximity tests, construct a set S of n high accuracy approximates to the roots of f(x).

We now outline the operations of Step [2]: Finding a highly isolated balanced splitting interval \hat{I} .

[2.1] Approximate magnitudes of all roots of f(x) by Turin's method.

[2.2]Compute the Sturm sequence and sign sequence, so we can count roots on real intervals fast.

[2.3] Find a 1/4-splitting point using a improved algorithm.

[2.4]Find a well isolated balanced splitting interval I, again using our improved algorithm.

[2.5]Use Graeff's method to construct a poly $\hat{f}(y) \operatorname{deg} n$ with highly isolated balanced splitting interval \hat{I} .

[2.6]Compute by the Sturm sequence method the number n' of roots of $\hat{f}(y)$ within \hat{I} .

Note:

Steps [2.3] and [2.4] use our improved $O(n \log^2 n)$ time algorithms, and these steps and the final step [5] require our fast root proximity tests (This improves on previous quadratic time algorithms of [Pan,89]).

We next outline the operations of Step [3]: Get high accuracy approx to factors $\hat{f}_1(y), \hat{f}_2(y)$ of $\hat{f}(y)$.

[3.1] Do Cauchy contour integration via FFT, using highly isolated balanced splitting interval $\hat{I}.$ [3.2]Solve NewtonUs equation which is a triangular Toeplitz system. This gives approx coef of factors of $\hat{f}(y)$ within error $\leq 2n/(1+\sigma)^n$.

[3.3]Using Newton Iterations, Get high accuracy approximations to factors of $\hat{f}(y)$ within error $\leq 2^{-\pi}$.

We give further details of our real root algorithm below. (Note we have renumbered the steps of algorithm, so the steps are in sequence.) The corresponding sections give detailed description and proof of each step. All calculations are to be made using log-precision $\pi = O(n(\mu + m + n))$.

INPUT A monic polynomial f(x) with degree n and log-precision m.

OUTPUT A set S of n rationals approximating the roots of f(x) within log-precision μ .

1. Eliminate any multiple zeros, by computing

$$\frac{f(x)}{\gcd(f(x),f'(x))}$$

in time $O(n \log^2 n)$ by applying Lemmas 3.1 and 3.2 and replacing f(x) with this new polynomial, which has the same distinct roots as f(x), but no multiple roots. Reassign n to be the degree of the new f(x). (See Subsection 3.3)

2. A real point s is a 1/4-splitting point if s is between the *i*th and i + 1th roots for some

 $n/4 \le i \le 3n/4.$

Find a 1/4-splitting point for the roots of f(x) guaranteed by Lemma 4.4 in time $O(n \log^2 n)$. Here we first compute the Sturm sequence in time $O(n \log^2 n)$ by Lemma 4.1. Then we determine of the sign sequence of the Sturm sequence, which is computable by multipoint evaluation in time $O(n \log^2 n)$ (Lemma 3.2). Then we apply Lemma 4.5 using $O(\log n)$ stages of binary search to determine the 1/4-splitting point from the linear coefficients of the Sturm sequence of f(x) At each stage we use the precomputed sign sequence of the Sturm sequence (described in Lemma 4.2) to count the number of roots within an interval. Thus each stage takes O(n) time. The total time for all $O(\log n)$ stages and including precomputation, is $O(n \log^2 n)$.

3. Approximate the magnitudes of all the roots by Turin's method in time $O(n \log^2 n)$ by applying Lemma 5.1. This determines the magnitude of each root r_i of f(x) to be within an interval

$$[r_i/(1-\frac{1}{n^{O(1)}}), r_i(1+\frac{1}{n^{O(1)}})].$$

- 4. Find a well isolated 1/6-splitting interval I, using the previously computed 1/4-splitting point and the approximate magnitudes of all the roots. Here we use our improved $O(n \log^2 n)$ time algorithm given by Lemma 6.1 (improving on the previous more than quadratic time algorithm of Pan [P 89]).
- 5. Use Graeff's method to construct in time $O(n \log^2 n)$ a polynomial $\hat{f}(y)$ of degree *n* with a highly isolated 1/6-splitting interval \hat{I} . $\hat{f}(y)$ is constructed by $\rho = O(\log n)$ stages of polynomial multiplication described in Lemma 7.1 requiring $O(n \log n)$ time per multiplication stage by Lemma 3.1. The variable transformation

$$\Phi(x) = y$$

involves various scalar calculations including reciprocals and taking 2^{ρ} -th powers of scalars.

- 6. Compute by the Sturm sequence method the number n' of roots of $\hat{f}(y)$ within \hat{I} .
- 7. Let Γ be the circle of diameter $length(\hat{I})$ on the complex plane intersecting the real line at the end points of the interval \hat{I} . For each $k = 1, \ldots, n'$, approximately evaluate the (complex) Cauchy contour integral:

$$s_k = \frac{1}{2\Pi\sqrt{-1}} \int_{z \in \Gamma} z^k \frac{\hat{f}(y)'}{\hat{f}(y)} dy$$

giving an approximation to the k-th power sum s_k of the roots of $\hat{f}(y)$. To approximately evaluate the integral, shift and deflate the polynomial $\hat{f}(y)$ by the variable mapping

$$y \mapsto (y - center(I))/radius(I)$$

so the resulting mapped interval is now [-1, 1]. This requires time $O(n \log n)$ by Lemmas 3.3, 3.4 and 3.5. Then evaluate the Cauchy contour integral of the transformed polynomial at the *n*th roots of unity, using a FFT in $O(n \log n)$ time. By Lemma 8.1 the error is

$$\leq 2n/(1+\sigma)^n,$$

for some constant $\sigma > 0$.

8. Using the Newton Identities given in Lemma 9.1 construct a triangular Toeplitz system relating the power sums of the n' roots of $\hat{f}(y)$ within the interval \hat{I} and the coefficients of a monic polynomial with these same

n' roots. Solve this triangular Toeplitz system in time $O(n \log n)$, thus determining approximate factor polynomial $\hat{f}_1(y)$ and

$$f_2(y) = f(y)/f_1(y)$$

where

$$deg(\hat{f}_1(y)) \ge n/6,$$

$$deg(\hat{f}_2(y)) \le n5/6,$$

with coefficient error between $\hat{f}(y)$ and $\hat{f}_1(y)\hat{f}_2(y)$ at most $2n/(1+\sigma)^n$.

9. Using $O(\log \pi)$ stages (where $\pi = O(n(\mu + m + n)))$ of Newton's Iteration method (Lemma 10.1), compute a high accuracy polynomial splitting to exponentially improve the accuracy of the previous low accuracy polynomial splitting. This yields approximate factor polynomials $\hat{f}_1(y), \hat{f}_2(y)$ where

$$deg(f_1(y)) \ge n/6,$$

$$deg(\hat{f}_2(y)) \le n5/6$$

and the error between the coefficients of $\hat{f}(y)$ and $\hat{f}_1(y)\hat{f}_2(y)$ is at most $2^{-\pi}$. Each stage requires polynomial multiplication and division taking time $O(n \log n)$ by Lemma 3.1. Therefore, the total time is

$$O(n\log n\log \pi) = O(n\log n\log(\mu + m + n))$$

assuming all calculations are made using log-precision

$$\pi = O(n(\mu + m + n)).$$

- 10. Apply our Real Root Algorithm recursively on polynomials $\hat{f}_1(y), \hat{f}_2(y)$, finding high accuracy approximations to the *n* roots $\hat{r}_1, \ldots, \hat{r}_n$ of $\hat{f}_1(y)$ and $\hat{f}_2(y)$ which differ from the roots of $\hat{f}_1(y)$ by at most $2^{-\pi}$.
- 11. Compute in $O(n \log n)$ time the set

$$\hat{S} = \bigcup_{i=1}^{n} \{ \Phi^{-1}(\tilde{r}_i) \}$$

of at most 2n rational points, containing a n size subset

$$S = \{\tilde{r}_1, \dots, \tilde{r}_n\}]$$

consisting of high accuracy approximations to the *n* roots $\{r_1, \ldots, r_n\}$ of f(x), which differ from the roots of f(x) by at most $2^{-\pi}$. The inverse variable transformation $\Phi^{-1}(y)$ involves taking 2^{ρ} -th roots. Since there

can be two possible real 2^{ρ} -th roots of a real number, \hat{S} contains at most 2n points. Each such scalar root computation can be done by $\rho = O(\log n)$ stages of taking square roots, which requires $O(\log n)$ time since square root is considered a basic operation in the arithmetic model of computation.

12. Find and output a set S of high accuracy approximations to the n roots of f(x) by evaluating f(x) at each point x ∈ Ŝ, and testing if f(x) is sufficiently small, say < 2^{-Ω(π)}. This can be done by a multipoint evaluation algorithm (stated in Lemma 3.2) in time O(n log² n) (improving on the previous more than quadratic time root proximity test of Pan [P 87, P 89] based on Turin's test). We prove the correctness of our surprisingly simple root proximity verification test in Theorem 11.1.

Note that computing the 2^{ρ} -th roots in step 11 requires an additive term of

$$O(\rho) = O(\log n)$$

further log-precision. Our algorithm will recurse at most $O(\log n)$ levels, thus requiring us to increase the required log-precision of calculations in the overall real root finding algorithm by an additive factor of only $O(\log^2 n)$.

In addition to the above comment, the extensive precision analysis of Schönhage [S 82], Ben-Or, Feig, Kozen and Tiwari, [BFK 86] as stated by Lemmas 3.8, 3.9, limit the required precision of all calculations made by our algorithm to log-precision

$$\pi = O(n(\mu + m + n)).$$

We have shown in the steps above that each recursive decomposition of a polynomial of degree n requires time at most

$$O(n(\log n)(\log n + \log \pi)) \le O(n(\log n)(\log n + \log b)),$$

where $b = m + \mu$, since

$$\log \pi \le O(\log(n(\mu + m + n))) \le O(\log n + \log(n^2(\mu + m))) \le O(\log n + \log b).$$

Thus, a recurrence equation for the arithmetic time complexity is:

$$T(n) \le T(n') + T(n-n') + O(n\log n(\log n + \log b)),$$

where

$$n/6 \le n' \le n5/6,$$

and T(1) = O(1). Thus,

$$T(n) \le O(n \log^2 n(\log n + \log b)),$$

proving our main Theorem 2.1.

By the known efficient reduction from the symmetric tridiagonal eigenvalue problem to the real root problem described in Subsection 1.2, **Corollary 2.1** There is an algorithm for the symmetric tridiagonal eigenvalue problem which has arithmetic time cost $O(n \log^2 n(\log n + \log b))$, where $b = m + \mu$, using arithmetic steps with log-precision

$$\pi = O(n(\mu + m + n)).$$

3 Preliminary Results

3.1 Arithmetic on Polynomials

All the polynomials considered in this paper are assumed univariate unless otherwise indicated. The following are well known results (see [AHU 74])

Lemma 3.1 There is an $O(n \log n)$ time algorithm for multiplication and division of two polynomials.

Lemma 3.2 There is an $O(n \log^2 n)$ time algorithm for computing the n point evaluation and also greatest common divisor(gcd) of two polynomials.

3.2 Translation, Deflation and Inversion Operations on Polynomials

There are efficient algorithms for analytic mappings such as translation, deflation, inversion, etc. of a polynomial. These will be used in our root finding algorithm. Let f(x) be a polynomial of degree n. In each of these operations we wish to compute, without loss of precision, the coefficients of the new polynomial given the coefficients of the original polynomial.

Lemma 3.3 There is an $O(n \log n)$ time algorithm for the variable translation mapping

 $x\mapsto x-\alpha$,

for real α , resulting in translated polynomial

$$g(y) = f(y - \alpha).$$

Lemma 3.4 There is an O(n) time algorithm for the variable deflation mapping $x \mapsto x/\alpha$, for real α , resulting in polynomial $g(y) = f(y/\alpha)$.

Lemma 3.5 There is an O(n) time algorithm for the variable inversion mapping

 $x \mapsto 1/x$,

for real α , resulting in translated polynomial

 $g(y) = y^n f(1/y).$

3.3 Reduction to Simplified Root Finding Problems

Here we review classical techniques for reduction to simplified root finding problems. A polynomial f(x) is *monic* if its highest order coefficient is 1, so it can be written

$$\prod_{i=1}^{n} (x - r_i)$$

where the r_i are the roots. Obviously, any polynomial can be made monic by dividing out the highest order coefficient without altering the roots. Also, any polynomial with rational coefficients can obviously be made into a polynomial with integer coefficients by simply multiplying the denominators of the rational coefficients.

Given a univariate polynomial f(x) of degree n with complex coefficients, we can construct a polynomial $f(x)f^*(x)$ (where the coefficients of $f^*(x)$ are the complex conjugates of the coefficients of f(x)) of degree 2n with real coefficients containing all the roots of f(x), thus efficiently reducing the problem of root finding in complex polynomials to the problem of root finding in polynomials with real coefficients.

A simple root r of a polynomial f(x) is a root with no multiplicity. Given an univariate polynomial f(x) of degree n with n' distinct zeros, we can construct a polynomial

$$\frac{f(x)}{\gcd(f(x),f'(x))}$$

with exactly the same distinct n' roots but no multiplicities, thus efficiently reducing the problem of root finding in polynomials with multiple roots to the problem of root finding in polynomials with only simple roots.

Thus, throughout this paper we generally assume the given polynomial f(x) is monic and has only integer coefficients and simple roots, say

$$r_1 < r_2 < \ldots < r_n.$$

3.4 Bounds on Roots: Root Separation

The *root separation* of a polynomial is the minimum distance between any two distinct roots. Mahler, 1964 proves:

Lemma 3.6 The minimum root separation of a polynomial of degree n and coefficient log-precision m is lower bounded by

$$\sqrt{3}n^{-(n+2)/2}2^{-m(n-1)} \le 2^{-(2n\log n+mn)}.$$

Cauchy in 1929 (see Householder, 1970 [H 70]) showed that

Lemma 3.7 Given a polynomial with coefficient log-precision m, the maximum magnitude of any root is $\leq 2^m$.

3.5 Bounded Precision Polynomial Approximation

Let f(x) be an approximation of f(x) up to log-precision π , that is, the coefficients of $\tilde{f}(x)$ differ from the coefficients of f(x) by at most $2^{-\pi}$, where

$$\pi = O(n(\mu + m + n)).$$

The following can be proven using the fact that a polynomial with real coefficients has roots which are either real or complex conjugate pairs.

Lemma 3.8 (Householder, 1970 [H 70], [BFK 86]) The roots of $\tilde{f}(x)$ differ from the roots of f(x) by at most $2^{-\mu}$.

Lemma 3.9 (Householder, 1970 [H 70], [BFK 86]) If the minimum root separation of f(x) is $> 2^{-\mu}$ and f(x) has all distinct real roots, then so does $\tilde{f}(x)$.

The following Lemmas are due to Schönhage [S 82], and Ben-Or, Feig, Kozen and Tiwari, 1986 [BFK 86].

Lemma 3.10 Given a monic polynomial f(x) of degree n with coefficient logprecision m, and suppose $f_1(x), \ldots, f_n(x)$ are monic polynomials such that the polynomial

$$f(x) - \prod_{i=1}^{n} f_i(x)$$

has degree n-1 and coefficient log-precision $\pi = n(m + \mu + 2\log n + 4)$, then $f_1(x), \ldots, f_n(x)$ need to have at most coefficient log-precision nm.

Lemma 3.11 Given a monic polynomial f(x) of degree n with coefficient logprecision m, and suppose $f_1(x), \ldots, f_n(x)$ are the approximate linear factors of f(x) using log-precision $O(n(\log n + m + \mu))$, then the coefficient size of

$$f(x) - \prod_{i=1}^{n} f_i(x)$$

 $is < 2^{-\mu}$.

In this paper we are mostly interested in the arithmetic complexity but we do not ignore the bit complexity. These above results limit the required precision all calculations need to be made to log-precision $\pi = O(n(\mu + m + n))$.

4 Sturm sequences and Root Isolation

Recall the following definitions: For any $\epsilon, 0 < \epsilon < 1/2$, an interval [s, s'] on the real line is an ϵ -splitting interval for the roots of f(x) if the interval [s, s']

contains exactly *i* roots of f(x), for some *i*, where $\epsilon n \leq i \leq (1 - \epsilon)n$ (see Figure 1). The ϵ -splitting is *balanced* if ϵ is constant.

A Sturm sequence of polynomials $f_0(x), f_1(x)$ is the sequence of polynomials

$$f_0(x), f_1(x), \ldots, f_k(x)$$

where for i = 1, 2, ..., k - 1,

$$f_{i+1}(x) = q_i(x)f_i(x) - f_{i-1}(x),$$

the $q_i(x)$ are linear, and $f_k(x)$ is constant. Sturm defined this sequence in 1829. See [BP 60] for a survey on Sturm sequences.

The (standard) Sturm sequence of polynomial f(x) is defined to be the Sturm sequence of

$$f(x) = f_0(x), f'(x) = f_1(x).$$

Since f'(x) has degree n-1, the Sturm sequence of f(x) has length k=n.

Note that the Sturm sequence of $f_0(x)$, $f_1(x)$ is similar to the remainder sequence generated by the Euclidean algorithm for the $gcd(f_0(x), f_1(x))$ except that in the case of the Sturm sequence, $f_{i+1}(x)$ is the negative of the remainder of the division of $f_{i-1}(x)$ by $f_i(x)$. Therefore, by simple modification (see Schwartz [Sc 80] for details) of the usual HGCD algorithms (see [AHU 74]) used to compute gcd,

Lemma 4.1 The Sturm sequence can be computed in time $O(n \log^2 n)$.

Note: The precision required of the Sturm sequence as defined above can be quite high; but this can be easily remedied by use of additional indeterminants as linear factors, yielding a Sturm sequence computation requiring lower precision; see Collins [C 66] and [BFK 86] and also Ben-Or and Tiwari [BT 90] for details.

The applications of Sturm sequences use the following lemma, attributed to Rolle; see Marden, 1966 [M 66], Collins and Loos [CL 82], and Mignotte [M 92]:

Lemma 4.2 If f(x) has real coefficients and all roots are real, then the roots of f'(x) are all real and they strictly interleave the roots of f(x).

For a real a, let V_a be the number of sign variations of the Sturm sequence

$$f_0(a), f_1(a), \ldots, f_k(a),$$

that is, the number of times

$$f_i(a) \cdot f_{i+1}(a) < 0.$$

The following is proven using the result of Rolle:

Lemma 4.3 (Jacobson, 1974) For any interval [a, b] of the real line, the number of real roots in this interval is $V_a - V_b$.

Let the zeros of the linear terms $q_i(x)$ be ordered

$$y_{i_1} \le y_{i_2} \le \ldots \le y_{i_k}$$

and let the roots of f(x) be ordered

$$r_1 < r_2 < \ldots < r_n.$$

For any fixed $\epsilon, 0 < \epsilon < 1/2$, a point s on the real line is an ϵ -splitting point for the roots of f(x) if $r_i < s < r_{i+1}$ for some

$$\epsilon n \le i \le (1 - \epsilon)n.$$

Ben-Or, Feig, Kozen and Tiwari [BFK 86] prove the remarkable result that:

Lemma 4.4 There is a j such that y_{i_j} is a 1/4-splitting point for the roots of f(x)

Using a binary search of $O(\log n)$ stages on the sequence

$$y_{i_1} \le y_{i_2} \le \ldots \le y_{i_k}$$

and applying Lemma 4.3 to count the number of roots of f(x) in the appropriate interval considered at each stage of this binary search, we get

Lemma 4.5 There is an $O(n \log^2 n)$ algorithm for finding a 1/4-splitting point for the roots of f(x).

5 Approximating The Magnitudes Of All the Roots

A method due to Turin in 1968 [T 68, T 75, T 84] can be used to determine approximations to the magnitudes of all the roots of a polynomial. Schönhage [S 82] describes an algorithm which uses Turin's method to approximating the magnitudes of all the roots by a certain ratio. This algorithm takes an input a polynomial f(x) of degree n, and for each root r of f(x), determines the magnitude of r to be within an interval [L, U], where

$$U/(2n) \le 2nL.$$

Pan [P 89] shows this algorithm takes $O(n \log n)$ time using a reduction to 2D convex hull, for which there are many known $O(n \log n)$ time algorithms[PS 85]. Pan [P 87] observes that $g = O(\log(\log(2n)/\log(1-\gamma^2)))$ iterations of Graeff's method (which is a technique involving polynomial powering described in Section 7) improves these root bounds to ratio $(1 + \gamma)$. Since for $\gamma = 1/n^{O(1)}$, $g = O(\log n)$, this gives the following result: **Lemma 5.1** Given a polynomial of degree n, there is a $O(n \log^2 n)$ algorithm which, for all i = 1, ..., n, determines the magnitude of each root r_i of f(x) to be within an interval $[L_i, U_i]$, where

$$U_i \le L_i(1+\gamma),$$

for $\gamma = 1/n^{O(1)}$.

6 Finding A Well-Isolated ϵ -Splitting Interval

Recall the following definitions: For any real $\alpha, \sigma, \delta > 0$, an interval $I = [\alpha - \delta, \alpha + \delta]$ is σ -isolated with respect to the roots of f(x) if the larger interval

 $[\alpha - (1+\sigma)\delta, \alpha + (1+\sigma)\delta]$

has no further roots of f(x) other than those contained already in I (see Figure 2). An interval is well isolated if it is σ -isolated, for $\sigma \geq \Omega(1/n)$ and is highly isolated if it is σ -isolated, for $\sigma \geq \Omega(1)$. The following is an improvement of Pan's [P 89] quadratic time algorithm for finding a well isolated balanced splitting interval.

Lemma 6.1 There is an $O(n \log^2 n)$ algorithm given a 1/4-splitting point, for finding a σ -isolated 1/6-splitting interval for the n real roots of f(x), where $\sigma = 2/((1 + \theta)n)$, for any constant $\theta > 0$.

Proof: Let $r_1 < r_2 < \ldots < r_n$ be the roots of f(x). Let $\gamma = ln(1+\theta)/n$,

where ln is the natural logorithm. Compute by Lemma 4.4 a rational s which is a 1/4-splitting point for the roots of f(x). Construct the shifted polynomial

$$g(y) = f(y - s)$$

(Note: the purpose of shifting by s is to insure the root distances are determined from s rather than 0. Also, note that it suffices for us to find a splitting interval for the shifted polynomial g(y), since for any interval containing k roots of g(y)the corresponding interval shifted by s contains k roots of f(x).) Compute by Lemma 5.1 the approximate root magnitudes of g(y), giving for each i = 1, ..., n, a lower bound L_i and upper bound $U_i = L_i(1 + \gamma)$ of the distance from s of each root r_i of f(x):

$$L_i \le |r_i - s| \le U_i$$

with

$$L_1 \leq L_2 \leq \ldots \leq L_n$$

Let $U_0 = 0$. We will consider the gaps between consecutive bounding intervals for the roots of g(y). We define gap *i* to be the interval $[U_i, L_{i+1}]$ if $L_{i+1} > U_i$ and otherwise the *empty* interval of length 0. (See Figure 3.) The length of gap i is

$$G_i = max(0, L_{i+1} - U_i)$$

for $0 \leq i \leq n-1$ and let the length of gap n be $G_n = \infty$. We say gap k dominates gaps i, \ldots, j , for $i \leq j$, if gap k has the largest length among these gaps i, \ldots, j .

Claim: Suppose for $k + 1 \le k'$, gap k dominates gaps $0, \ldots, k' - 1$, but k' = n or gap k does not dominate the gap k'. If there are exactly R roots of g(y) of magnitude at least L_{k+1} and at most $U_{k'}$, where $\epsilon n \le R$ and $\epsilon < 1/2$, then one of

$$I^{+} = [L_{k+1}, U_{k'}], I^{-} = [-U_{k'}, -L_{k+1}]$$

is a σ -isolated $\epsilon/2$ -splitting interval for g(y). (See Figure 4a.) If there are exactly R' roots of g(y) of magnitude at least L_{k+1} and at most U_n , where $\epsilon'n \leq R' \leq (1-\epsilon')n$ and $\epsilon' < 1/2$, then one of

$$I' = [-U_k, U_{k'}], I'' = [-U_{k'}, U_k]$$

is a σ -isolated $\epsilon'/2$ -splitting interval for g(y), where $\sigma = 2/((1 + \theta)n)$. (See Figure 4b.)

Proof: In accordance with the assumptions of the claim, we have

$$G_k \ge G_i$$

for each i = 0, ..., k' - 1. For each i = k + 1, ..., k' - 1, we have the recurrence equation:

$$U_{i+1} \le (U_i + G_k)(1+\gamma),$$

giving the bound

$$U_{k'} \le G_k \sum_{i=1}^{k'} (1+\gamma)^i \le nG_k (1+\gamma)^n \le nG_k (1+\theta)$$

 since

$$(1+\gamma)^{(1/\gamma)} \le e$$

and

$$(1+\gamma)^n \le (1+\gamma)^{(1/\gamma)(\gamma n)} \le e^{\gamma n} \le 1+\theta$$

for $\gamma = ln(1+\theta)/n$. Thus we have

$$|I^+| = |I^-| \le U_{k'} - U_k \le U_{k'} \le nG_k(1+\theta) \le G_k/(2\sigma),$$

for $\sigma = 2/((1 + \theta)n)$, so the intervals I^+, I^- each have radius $\delta = |I^+|/2 = |I^-|/2 \le G_k/(2\sigma)$. Also we have

$$|I'| = |I''| \le 2U_{k'} \le 2nG_k(1+\theta) \le G_k/\sigma,$$

so the intervals I', I'' each have radius $\delta' = |I'|/2 = |I''|/2 \leq G_k/\sigma$, where $\delta' \geq \delta$. Hence $G_k \geq \sigma \delta'$, so the intervals

$$[U_{k'}, U_{k'} + \sigma\delta'], [-U_{k'} - \sigma\delta', -U_{k'}],$$
$$[L_{k+1} - \sigma\delta', L_{k+1}], [-L_{k+1}, -L_{k+1} + \sigma\delta']$$

contain no roots (see figures 4a and 4b). Thus each of the intervals I^+, I^-, I', I'' are surrounded by empty intervals of size $\sigma\delta' \geq \sigma\delta$ containing no roots, so it follows that each of these intervals are σ -isolated. Suppose there are exactly Rroots of magnitude at least L_{k+1} and at most $U_{k'}$, where $\epsilon n \leq R$ for $\epsilon < 1/2$. By the pigeon hole principal, either (i) at least R/2 of these R roots are nonnegative or (ii) at least R/2 of these R roots are non-positive. If $R \leq (1-\epsilon)n$, then one of the intervals I^+ or I^- has at least $R/2 \geq (\epsilon/2)n$ roots and at most $R \leq (1-\epsilon)n$ roots of g(y). Else if $R > (1-\epsilon)n$, then one of the intervals I^+ or I^- has at least $R/2 \geq (1-\epsilon)n/2$ roots and (since s is a 1/4-splitting point, both $[-\infty, s]$ and $[s, \infty]$ have at most 3n/4 roots each) at most 3n/4 roots of g(y). Since $\epsilon/2 \leq 1-3/4 = 1/4$ for $\epsilon < 1/2$, we conclude in either case that one of the intervals I^+ or I^- is a σ -isolated $\epsilon/2$ -splitting interval of g(y).

Now suppose there are exactly R' roots of magnitude at least L_{k+1} and at most U_n , for $\epsilon'n \leq R' \leq (1-\epsilon')n$ and $\epsilon' < 1/2$. By the pigeon hole principal, either (i) at most R'/2 of these R' roots are non-negative or (ii) at most R'/2 of these R' roots are non-positive. Then one of the intervals I' or I'' has at least $n - R' \geq \epsilon' n$ roots and at most $R'/2 + (n - R') = n - R'/2 \leq (1 - \epsilon'/2)n$ roots. Since $\epsilon' \geq 1 - (1 - \epsilon'/2) = \epsilon'/2$, we conclude one of the intervals I' or I'' is a σ -isolated $\epsilon'/2$ -splitting interval of g(y). This completes the proof of the Claim.

We will use the above claim to complete our proof of Lemma 6.1 as follows. Fix a gap k_1 , for $0 \le k_1 \le \lfloor 2n/3 \rfloor$, which dominates gaps $0, \ldots, \lfloor 2n/3 \rfloor$. Let k_2 be the minimum number $> \lfloor 2n/3 \rfloor$ such that gap k_1 does not dominate the gap k_2 , but dominates the gaps $\lfloor 2n/3 \rfloor + 1, \ldots, k_2 - 1$ (note that if gap k_1 dominates all the gaps $\lfloor 2n/3 \rfloor + 1, \ldots, n-1$, then $k_2 = n$).

CASE 1. Consider the case that $k_1 \leq \lfloor n/3 \rfloor$. Let

$$I^+ = [L_{k_1+1}, U_{k_2}], I^- = [-U_{k_2}, -L_{k_1+1}].$$

Since there are R roots of magnitude at least L_{k_1+1} and at most U_{k_2} , where $n/3 \leq R$, all the requirements in first part of the claim are satisfied for $\epsilon = n/3$, so either I^+ or I^- is σ -isolated 1/6-splitting interval.

CASE 2. Next consider the case that $k_1 > \lfloor n/3 \rfloor$. Let

$$I' = [-U_{k_2}, U_{k_1}], I'' = [-U_{k_1}, U_{k_2}]$$

Since there are R' roots of magnitude at least L_{k_1+1} and at most U_n , where $n/3 \leq R' \leq 2n/3$, all the requirements in the second part of the claim are satisfied for $\epsilon' = n/3$, so either I' or I'' is σ -isolated 1/6-splitting interval.

In either case, we can determine which interval to use by applying Lemma 4.3.

7 Obtaining a Highly Isolated Interval by Polynomial Powering

The following is known as Graeff's Method, but is actually due to Dandelin, 1826. Given a monic polynomial $f_0(x) = \prod_{i=1}^n (x - r_i)$ of degree n, let

$$f_i(x) = f_{i-1}(\sqrt{x}) \cdot f_{i-1}(-\sqrt{x})$$

for i > 0. Note that

$$f_1(x) = (-1)^n \prod_{i=1}^n (x - r_i^2),$$

so $f_1(x)$ has the same degree *n* but the roots of $f_1(x)$ are the squares of the roots of $f_0(x)$. Thus, for any i > 0, $f_i(x) = (-1)^{ni} \prod_{i=1}^n (x - r_i^{2^i})$, so $f_i(x)$ has the same degree *n* but the roots of $f_i(x)$ are the 2^{*i*} th powers of the roots of $f_0(x)$.

Given a well isolated ϵ -splitting interval $I = [\alpha - \delta, \alpha + \delta]$ for the roots of f(x), let $x = \alpha + y$, and let

$$g_0(y) = y^n f(\alpha + 1/y) / f(\alpha)$$

be the monic polynomial of degree *n* derived from f(x). Let $\rho = \sigma \log n$, for any constant $\sigma > 0$. Applying Graeff's Method to g_0 , we compute

$$g_i(y) = g_{i-1}(\sqrt{y})g_{i-1}(-\sqrt{y})$$

for $i = 1, 2, ..., \rho$, resulting in a degree *n* polynomial $\hat{f}(y) = g_{\rho}(y)$ which has roots which are the 2^{ρ} th powers of the roots of $g_0(y)$. Note that the corresponding interval \hat{I} for $\hat{f}(y)$ is σ -isolated, ϵ -splitting interval for the roots of $\hat{f}(y)$. The variable transformation $\Phi(x) = y$ involves scalar calculations including reciprocals and taking 2^{ρ} -th powers of scalars.

Lemma 7.1 Given well isolated ϵ -splitting interval I for the roots of f(x), for any constant $\sigma > 0$, there is an $O(n \log^2 n)$ algorithm for constructing a degree n polynomial $\hat{f}(y)$ and an interval \hat{I} which is a σ -isolated ϵ -splitting interval for the roots of $\hat{f}(y)$. Furthermore, a set of 2n points containing all the roots of f(x) can be obtained by the inverse variable transformation

$$\Phi^{-1}(y) = x$$

involving scalar calculations including reciprocals and taking 2^{ρ} -th roots of scalars.

FFT Approximations to Contour Integrals 8

Let $r_1, \ldots, r_{n'}$ be the real roots of monic polynomial f(x) within the interval I. Let Γ be a circle on the complex plane of diameter length(I) and such that the endpoints of interval I are on Γ (see figures 5a and 5b).

The Cauchy formula states that if Γ is a closed curve on the complex plane, then

$$s_k = \frac{1}{2\pi\sqrt{-1}} \int_{z \in \Gamma} z^k \frac{f'(z)}{f(z)} dz$$

where

$$s_k = r_1^k + \ldots + r_{n'}^k$$

is the kth power sum of the roots in I. Schönhage [S 82], (also see Pan [P 87]) shows

Lemma 8.1 If Γ is the unit disk and interval I is σ -isolated, then the integral can be approximated by the Nth roots of unity within error $\leq 2n/(1+\sigma)^N$.

First shift and deflate the polynomial f(x) by the variable mapping

 $x \mapsto (x - center(I))/radius(I)$

so the resulting mapped interval is [-1, 1] Then evaluate the Cauchy contour integral at the roots of unity by a FFT in $O(n \log n)$ time, thus giving:

Lemma 8.2 Given a degree n polynomial f(x) and an interval I which is a σ -isolated interval for the roots of f(x), for a constant $\sigma > 0$, then in time $O(n \log n)$ the n power sums of the roots of f(x) can all be computed within precision $< 2n/(1+\sigma)^n$.

Polynomial Splitting Using The Newton Iden-9 tities

Given the power sums s_1, \ldots, s_n of a monic polynomial

-

$$f(x) = \sum_{i=0}^{n} c_i x^i,$$

with $c_n = 1$, the coefficients of f(x) can be related to the power sums s_1, \ldots, s_n of the roots of f(x) by the following linear system, known as Newton's Identities:

[1				٦	$\int c_{n-1}$	1	s_1	1
s_1	2				c_{n-2}		s_2	
s_2	s_1	3			c_{n-3}	=	s_3	
	· · .	·	·		:		:	
s_n	s_{n-1}		s_1	n	c_0		s_n	

Lemma 9.1 Given power sums of a monic polynomial f(x) within precision $\leq 2n/(1+\sigma)^n$, we can compute the coefficients of f(x) within the same order of accuracy.

This linear system is nearly a triangular Toeplitz system, and can be solved by applying known $O(n \log n)$ algorithms [BP 86].

Lemma 9.2 Given a degree n polynomial f(x) and an interval I which is a σ isolated ϵ -splitting interval for the roots of f(x), for a constant $\sigma > 0, 0 < \epsilon < 1$,
then in time $O(n \log n)$, f(x) can be approximately separated into a product $g_1(x)g_2(x)$ where

$$\epsilon n \leq deg(g_1(x)),$$

$$deg(g_2(x)) \le (1-\epsilon)n,$$

and the coefficient error between f(x) and $g_1(x)g_2(x)$ is at most $2n/(1+\sigma)^n$.

10 High Accuracy Calculations Using Newton Iteration

10.1 High Accuracy Polynomial Splitting Using Newton Iteration

We will apply the Newton's iteration method developed by Schönhage [S 82] to exponentially improve the accuracy of a low accuracy polynomial splitting.

Lemma 10.1 Given a degree n polynomial f(x) and an interval I which is a σ isolated ϵ -splitting interval for the roots of f(x), for constants $\sigma > 0, 1 > \epsilon > 0$,
and where f(x) is approximately separated into $f_1(x)f_2(x)$ where

$$\epsilon n \le deg(f_1(x)),$$

 $deg(f_2(x)) \le (1-\epsilon)n,$

and coefficient error between f(x) and $f_1(x)f_2(x)$ is at most $2n/(1+\sigma)^n$, then in time $O(n \log n \log \pi)$, f(x) can be approximately separated as $f_1(x)f_2(x)$, where

$$\epsilon n \leq deg(f_1(x)), deg(f_2(x)) \leq (1-\epsilon)n,$$

so that the coefficient error between f(x) and $f_1(x)f_2(x)$ is at most $2^{-\pi}$.

Note that this algorithm requires $O(\log \pi)$ stages, where each stage requires polynomial multiplication and division taking time $O(n \log n)$ by Lemma 3.1. Therefore the total time is $O(n \log n \log \pi)$. We can apply this lemma to obtain arbitrarily high precision polynomial splittings.

10.2 Improving the Accuracy of Root Approximations Using Newton Iteration

Optionally, we can also apply a Newton's iteration method developed by Schönhage [S 82] to exponentially improve the accuracy of low accuracy root approximations.

Lemma 10.2 Given a degree n polynomial f(x) with n approximate roots which have distance from the roots of at most $1/(1+\sigma)^n$ for $\sigma > 0$ then in time $O(n \log n \log \pi)$, we can find n approximate roots

 $\tilde{r}_1,\ldots,\tilde{r}_n$

which have distance from the roots of at most $2^{-\pi}$.

Note that this algorithm requires $O(\log \pi)$ stages, where each stage requires n point polynomial evaluation (Lemma 3.2) taking time $O(n \log^2 n)$. By this method however, the total time is $O(n \log^2 n \log \pi)$.

11 Fast Root Proximity Verification

Note that there may be two real *N*-th roots of a real number, for $N \ge 2$. Thus, to apply Lemma 7.1, we need a way to test, given a real point, whether it is close to a root of f(x). (see figure 6.) Pan [P 87, P 89] utilized a costly proximity test due to Turin requiring $\Omega(n \log^2 n)$ time per test, and a total time of $\Omega(n^2 \log^2 n)$ time for the 2*n* tests. The following improves on Turin's test:

Theorem 11.1 Let f(x) be a polynomial of degree n with all real roots and with real coefficients of log-precision m. Let S be a set of real points where we wish to test which points are within a given sufficiently small distance $2^{-\pi}$ of a root of f(x), where $\pi = O(n(\mu + n + m))$. Then all these tests can be done in time $O(n \log^2 n)$.

Proof: We reduce the task to multipoint evaluation, for which there are $O(n \log^2 n)$ time algorithms (Lemma 3.2).

Lemma 11.1 Given a polynomial f(x) of degree n with all real roots and coefficient log-precision m, if we find a real α such that $|f(\alpha)| < 2^{-\tau}$, for sufficiently large τ , then the closest distance Δ_n from α to a root of f(x) is at most $2^{m-\tau}$ for n = 1 and at most $n2^{n-(\tau-m+n(n+1)/2)/n}$ for n > 1.

Proof : For fixed $m, \beta \ge 1$, we show by induction on n that if α is further than $\Delta_n = n2^{n-\beta}$ from a root of f(x) then $|f(\alpha)| > 2^{-\tau_n}$ for $\tau_1 = \beta + m - 1$ and

$$\tau_n = n\beta + m - n(n+1)/2 \quad for \quad n > 1$$

(see Figures 7,8).

In the base case n = 1, $f(x) = c_0 + c_1 x$ is a linear function with $c_1 \neq 0$, so

$$|f'(x)| = |c_1| \ge 2^{1-m}.$$

Thus |f(x)| grows by a rate of at least 2^{-m} , so

$$|f(\alpha)| \ge |c_1| \Delta_1 \ge 2^{-m} 2^{1-\beta} \ge 2^{-\tau_1},$$

for $\tau_1 = \beta + m - 1$.

Now consider an f(x) of arbitrary degree n > 1. Since we have assumed that f(x) has real coefficients and all roots are real, by Rolle's result (Lemma 4.2), the roots of f'(x) are all real and they strictly interleave the roots of f(x). Choose r to be the root of f(x) either just below α or just above α , such that f'(x) is not zero between α and r. Let I be the interval between α and r, not containing r but containing α . Thus, there are at most two roots, say r_1, r_2 of f'(x) where r_1, r_2 are not on I but are of distance $\leq \Delta_{n-1}$ from a point on I. Let I' be the points of I of distance $\geq \Delta_{n-1}$ from a root of f'(x). Note that

$$|I'| \ge \Delta_n - 2\Delta_{n-1} > n2^{n-\beta} - (n-1)2 \cdot 2^{(n-1)-\beta}$$
$$\ge 2^{n-\beta}(n-(n-1)) \ge 2^{n-\beta}.$$

Since f'(x) has degree n-1, by the induction hypothesis, $|f'(x)| \ge 2^{-\tau_{n-1}}$ for all $x \in I$ of distance $> \Delta_{n-1} = (n-1)2^{n-1-\beta}$ from r_1 or r_2 . Thus

$$|f(\alpha)| \ge 2^{-\tau_{n-1}} |I'| \ge (2^{-\tau_{n-1}})(2^{n-\beta}) \ge 2^{n-\beta-\tau_{n-1}} \ge 2^{-\tau_n}$$

for τ_n , requiring τ_n to satisfy the recurrence equation $\tau_n = \tau_{n-1} + \beta - n$ for n > 1, and $\tau_1 = \beta + m - 1$. This gives

$$\tau_n = \tau_1 + \sum_{i=2}^n (\beta - i) = (\beta + m - 1) + ((n - 1)\beta + 1 - n(n + 1)/2)$$
$$= n\beta + m - n(n + 1)/2 \quad for \quad n > 1.$$

12 Application of the Real Root Problem: the Symmetric Eigenvalue Problem in Sparse and Structured Matrices

Root finding has many applications, and one of the most important of these is finding the eigenvalues of a matrix. The eigenvalues are the roots of the characteristic polynomial of the matrix, which can found by a symbolic computation on the determinant. The characteristic polynomial of a matrix A is $det(A - I\lambda)$, where λ is an indeterminant.

Here consider various such classes of sparse and structured matrices occurring in practice which have special structure that allow the characteristic polynomial to be computed significantly faster than time $O(n^3)$. We can apply Theorem 2.1 to efficiently solve the symmetric eigenvalue problem for these classes of matrices. Thus, given efficient algorithms for the real root problem, we get efficient algorithms for the symmetric eigenvalue problem for these classes of matrices.

Eigenvalues are used in many engineering and scientific applications, including vibration analysis in structures, stability analysis, etc. The *symmetric eigenvalue problem* is: given a symmetric matrix (or more generally, a Hermitian matrix), find all the eigenvalues; which are all real in this case. Symmetric matrices and the corresponding symmetric eigenvalue problems occur naturally and frequently in applications and in fact most application programs for eigenvalues are for the symmetric eigenvalue problem. For example in most of the cases where the matrices are derived from the solution of discretized PDEs, circuit problems, structure problems, and in signal processing, the resulting matrices are generally symmetric. Moreover, many large matrices occurring in practice have a special structure which allow the characteristic polynomial to be computed in nearly quadratic time. In addition to be generally symmetric, they often fall into one of two classes:

- 1. Dense structured matrices (see [BA 80, BGY 80, PR 87]). A matrix A is Toeplitz if $A_{i,j} = A_{i+k,j+k}$ for each k where the matrix elements are defined. Define an $n \times n$ matrix to have displacement rank r if it can be written as the sum of r terms, where each term is the product of a lower triangular Toeplitz matrix and an upper triangular Toeplitz matrix. Structured matrices, and in particular Toeplitz and bounded displacement rank matrices arise frequently in signal processing, coding theory, data compression, and algebraic computation applications. Pan [Pa 90] gave $O(n^2 \log n \log \log n)$ algorithms for computing the characteristic polynomial of these class of matrices.
- 2. A class of $n \times n$ matrices is *sparse* if they have O(n) non-zeros. Sparse matrices arise from, for example, VLSI circuit problems, structure problems and discretization of d = 2, 3 dimensional PDEs, Canny, Kaltofen and Laksman [CKL 89] have applied Wiedemann's method of solving sparse linear systems (see [KS 91]) to computing the characteristic polynomial of sparse matrices in $O(n^2 \log^2 n)$ time.

13 Conclusion

We have upper bounded the arithmetic complexity of the real root problem to be nearly the same as basic arithmetic operations on polynomials. We have shown that there is an algorithm for the real root problem which has time cost $O(n \log^2 n(\log n + \log b))$ in the arithmetic model where $b = m + \mu$. This is with polylog factors of optimality. There are number of immediate extensions:

- 1. improving the sequential boolean complexity of the real root problem,
- 2. improving the parallel complexity of the real root problem.

We have shown that our real root algorithm requires only the moderate bound of $\pi = O(n(\mu + m + n))$ bits of precision to carry out our computations, similar that required by other related root finding algorithms. Thus the Boolean complexity of our algorithm is a multiplicative factor of $M(\pi)$ more than our arithmetic complexity, where

$$M(\pi) = O(\pi(\log \pi) \log \log \pi)$$

is the bit complexity for multiplication of integers of length π . Ben-Or and Tiwari [BT 90] investigated the Boolean complexity of the real root problem, giving, for $b = m + \mu$ and b' = n + b, a bound of

$$O(n\log^2 nM(nb'))\log^2 b) \le O(n^2b'(\log^2 b)(\log b')\log^2 n\log\log b')$$

Boolean operations. Bini and Pan [BP 91, BP 92] recently developed an efficient algorithm for the symmetric tridiagonal matrix eigenvalue problem, which has Boolean cost of $O(n^2 M(b) \log^2 b) = O(n^2 b (\log^3 b) \log \log b)$. Using the known efficient reduction from the real root problem to the symmetric tridiagonal matrix eigenvalue problem describe in Subsection 1.2, the resulting real root algorithm of Bini and Pan [BP 91, BP 92] has the same Boolean cost as for the symmetric tridiagonal matrix eigenvalue problem. Although Bini and Pan modestly view their work as a matrix reformulation of the Ben-Or and Tiwari [BT 90] algorithm, in fact they have a reduction in Boolean cost which remains the best known Boolean cost bound. In contrast, our real root algorithm has a single logarithmic factor more Boolean complexity, namely

$$O(M(nb')n\log^2 n\log b') = O(n^2b'(\log^2 n)(\log^2 b')\log\log b').$$

Thus there remains the open problem of further reducing the Boolean cost of the real root problem.

Our real root algorithm can be executed in parallel. Our most costly operation which respect to parallel arithmetic complexity in the $O(\log n)$ recursive levels is the Sturm sequence evaluation. In a subsequent paper we show that parallelization of the techniques of this paper and application of a parallel algorithm of Reif [R 93d] for inverse of various structured matrices including Toeplitz can be used to get an efficient parallel arithmetic algorithm for the real root problem.

It remains an open problem to determine a similarly efficient algorithm in the arithmetic model for the general root problem with complex roots.

14 Acknowledgments

The Author wishes to thank Ken Robinson for his excellent help in editing the paper, Steve Tate, Hongyan Wang, Shenfeng Chen, Salman Azhar, and especially Deganit Armon for their help in providing technical edits for this paper. Thanks to Andrew Neff for helpful technical comments. Also, I wish to thank Dario Bini and Victor Pan for pointing out the known relationship between the real root problem and the symmetric tridiagonal eigenvalue problem.
