October 2008

Resource misallocation can lower aggregate total factor productivity (TFP). We use micro data on manufacturing establishments to quantify the potential extent of misallocation in China and India compared to the U.S. Compared to the U.S., we measure sizable gaps in marginal products of labor and capital across plants within narrowly-defined industries in China and India. When capital and labor are hypothetically reallocated to equalize marginal products to the extent observed in the U.S., we calculate manufacturing TFP gains of 30-50% in China and 40-60% in India.

* We are indebted to Ryoji Hiraguchi and Romans Pancs for phenomenal research assistance, and to numerous seminar participants, referees, and the editors for comments. We gratefully acknowledge the financial support of the Kauffman Foundation. Hsieh thanks the Alfred P. Sloan Foundation and Klenow thanks SIEPR for financial support. The research in this paper on U.S. manufacturing was conducted while the authors were Special Sworn Status researchers of the U.S. Census Bureau at the California Census Research Data Center at UC Berkeley. Research results and conclusions expressed are those of the authors and do not necessarily reflect the views of the Census Bureau. This paper has been screened to insure that no confidential data are revealed. Emails: chsieh@chicagogsb.edu and pete@klenow.net.

I. Introduction

Large differences in output per worker between rich and poor countries have been attributed, in no small part, to differences in Total Factor Productivity (TFP).¹ The natural question then is: what are the underlying causes of these large TFP differences? Research on this question has largely focused on differences in technology within representative firms. For example, Howitt (2000) and Klenow and Rodríguez-Clare (2005) show how large TFP differences can emerge in a world with slow technology diffusion from advanced countries to other countries. These are models of *within*-firm inefficiency, with the inefficiency varying across countries.

A recent paper by Restuccia and Rogerson (2008) takes a different approach. Instead of focusing on the efficiency of a representative firm, they suggest that misallocation of resources across firms can have important effects on aggregate TFP. For example, imagine an economy with two firms that have identical technologies but in which the firm with political connections benefits from subsidized credit (say from a state-owned bank) and the other firm (without political connections) can only borrow at high interest rates from informal financial markets. Assuming that both firms equate the marginal product of capital with the interest rate, the marginal product of capital of the firm with access to subsidized credit will be lower than the marginal product of the firm that only has access to informal financial markets. This is a clear case of capital misallocation: aggregate output would be higher if capital was reallocated from the firm with a low marginal product to the firm with a high marginal product. The misallocation of capital results in low aggregate output per worker and TFP.

Many institutions and policies can potentially result in resource misallocation. For example, the McKinsey Global Institute (1998) argues that a key factor behind low productivity in Brazil's retail sector is labor market regulations driving up the cost of labor for supermarkets relative to informal retailers. Despite their low productivity, the lower cost of labor faced by informal sector retailers makes it possible for them to command a large share of the Brazilian retail sector. Lewis (2004) describes many similar case studies from the McKinsey Global Institute.

¹ See Caselli (2005), Hall and Jones (1999), and Klenow and Rodríguez-Clare (1997).

Our goal in this paper is to provide quantitative evidence on the potential impact of resource misallocation on aggregate TFP. We use a standard model of monopolistic competition with heterogeneous firms, essentially Melitz (2003) without international trade, to show how distortions that drive wedges between the marginal products of capital and labor across firms will lower aggregate TFP.² A key result we exploit is that *revenue* productivity (the product of physical productivity and a firm's output price) should be equated across firms in the absence of distortions. To the extent revenue productivity differs across firms, we can use it to recover a measure of firm-level distortions.

We use this framework to measure the contribution of resource misallocation to aggregate manufacturing productivity in China and India versus the U.S. China and India are of particular interest not only because of their size and relative poverty, but because they have carried out reforms that may have contributed to their rapid growth in recent years.³ We use plant-level data from the Chinese Industrial Survey (1998-2005), the Indian Annual Survey of Industries (1987-1994) and the U.S. Census of Manufacturing (1977, 1982, 1987, 1992, and 1997) to measure dispersion in the marginal products of capital and labor within individual 4-digit manufacturing sectors in each country. We then measure how much aggregate manufacturing output in China and India could increase if capital and labor were reallocated to equalize marginal products across plants within each 4-digit sector *to the extent observed in the U.S.* The U.S. is a critical benchmark for us, as there may be measurement error and factors omitted from the model (such as adjustment costs and markup variation) that generate gaps in marginal products even in a comparatively undistorted country such as the U.S.

We find that moving to "U.S. efficiency" would increase TFP by 30-50% in China and 40-60% in India. The output gains would be roughly twice as large if capital accumulated in response to aggregate TFP gains. We find that deteriorating allocative efficiency may have shaved 2% off Indian manufacturing TFP growth from 1987 to 1994, whereas China may have boosted its TFP 2% per year over 1998-2005 by

² In terms of the resulting size distribution, the model is a cousin to the Lucas (1978) span of control model.

³ For discussion of Chinese reforms see Young (2000, 2003) and *The Economist* (2006a). For Indian reforms see Kochar et al. (2006), *The Economist* (2006b), and Aghion et al. (2008). Dobson and Kashyap (2006), Farrell and Lund (2006), Allen et al. (2007), and Dollar and Wei (2007) discuss how capital continues to be misallocated in China and India.

winnowing its distortions. In both India and China, larger plants within industries appear to have higher marginal products, suggesting they should expand at the expense of smaller plants. The pattern is much weaker in the U.S.

Although Restuccia and Rogerson (2008) is the closest predecessor to our investigation in model and method, there are many others.⁴ In addition to Restuccia and Rogerson, we build on three papers in particular. First, we follow the lead of Chari, Kehoe and McGrattan (2007) in inferring distortions from the residuals in first order conditions. Second, the distinction between a firm's physical productivity and its revenue productivity, highlighted by Foster, Haltiwanger, and Syverson (2008), is central to our estimates of resource misallocation. Third, Banerjee and Duflo (2005) emphasize the importance of resource misallocation in understanding aggregate TFP differences across countries, and present suggestive evidence that gaps in marginal products of capital in India could play a large role in India's low manufacturing TFP relative to the U.S.⁵

The rest of the paper proceeds as follows. We sketch a model of monopolistic competition with heterogeneous firms to show how the misallocation of capital and labor can lower aggregate TFP. We then take this model to the Chinese, Indian, and U.S. plant data to try to quantify the drag on productivity in China and India due to misallocation in manufacturing. We lay out the model in section II, describe the datasets in section III, and present potential gains from better allocation in section IV. In section V we try to assess whether greater measurement error in China and India could explain away our results. In section VI we make a first pass at relating observable policies to allocative efficiency in China and India. In section VII we explore alternative explanations besides policy distortions and measurement error. We offer some conclusions in section VIII.

⁴ A number of other authors have focused on specific mechanisms that could result in resource misallocation. Hopenhayn and Rogerson (1993) studied the impact of labor market regulations on allocative efficiency; Lagos (2006) is a recent effort in this vein. Caselli and Gennaioli (2003) and Buera and Shin (2008) model inefficiencies in the allocation of capital to managerial talent, while Guner, Ventura and Xu (2008) model misallocation due to size restrictions. Parente and Prescott (2000) theorize that low TFP countries are ones in which vested interests block firms from introducing better technologies.

⁵ See Bergoeing, Kehoe, Kehoe, and Soto (2002), Galindo, Schiantarelli, and Weiss (2007), Bartelsman, Haltiwanger, and Scarpetta (2008), and Alfaro, Charlton and Kanczuk (2008) for related empirical evidence in other countries.

II. Misallocation and TFP

This section sketches a standard model of monopolistic competition with heterogeneous firms to illustrate the effect of resource misallocation on aggregate productivity. In addition to differing in their efficiency levels (as in Melitz, 2003), we assume that firms potentially face different output and capital distortions.

We assume there is a single final good Y produced by a representative firm in a perfectly competitive final output market. This firm combines the output Y_s of S manufacturing industries using a Cobb-Douglas production technology:

$$(2.1) \quad Y = \prod_{s=1}^S Y_s^{\theta_s}, \text{ where } \sum_{s=1}^S \theta_s = 1.$$

Cost minimization implies:

$$(2.2) \quad P_s Y_s = \theta_s P Y.$$

Here, P_s refers to the price of industry output Y_s and $P \equiv \prod_{s=1}^S \left(\frac{P_s}{\theta_s} \right)^{\theta_s}$ represents the price of the final good (the final good is our numeraire, so $P = 1$). Industry output Y_s is itself a CES aggregate of M_s differentiated products:

$$(2.3) \quad Y_s = \left(\sum_{i=1}^{M_s} Y_{si}^{\frac{\sigma-1}{\sigma}} \right)^{\frac{\sigma}{\sigma-1}}.$$

The production function for each differentiated product is given by a Cobb-Douglas function of firm TFP, capital, and labor:

$$(2.4) \quad Y_{si} = A_{si} K_{si}^{\alpha_s} L_{si}^{1-\alpha_s}$$

Note that capital and labor shares are allowed to differ across industries (but not across firms within an industry).⁶

Since there are two factors of production, we can separately identify distortions that affect both capital and labor from distortions that change the marginal product of one of the factors relative to the other factor of production. We will denote distortions that increase the marginal products of capital *and* labor by the same proportion as an output distortion τ_Y . For example, τ_Y would be high for firms that face government restrictions on size or high transportation costs, and low in firms that benefit from public output subsidies. In turn, we will denote distortions that raise the marginal product of capital relative to labor as the capital distortion τ_K . For example, τ_K would be high for firms that do not have access to credit, but low for firms with access to cheap credit (by business groups or state-owned banks).

Profits are given by

$$(2.5) \quad \pi_{si} = (1 - \tau_{Ysi})P_{si}Y_{si} - wL_{si} - (1 + \tau_{Ksi})RK_{si}.$$

Note that we assume all firms face the same wage, an issue we will return to later. Profit maximization yields the standard condition that the firm's output price is a fixed markup over its marginal cost:

$$(2.6) \quad P_{si} = \frac{\sigma}{\sigma - 1} \left(\frac{R}{\alpha_s} \right)^{\alpha_s} \left(\frac{w}{1 - \alpha_s} \right)^{1 - \alpha_s} \frac{(1 + \tau_{Ksi})^{\alpha_s}}{A_{si}(1 - \tau_{Ysi})}.$$

The capital-labor ratio, labor allocation, and output are given by:

$$(2.7) \quad \frac{K_{si}}{L_{si}} = \frac{\alpha_s}{1 - \alpha_s} \cdot \frac{w}{R} \cdot \frac{1}{(1 + \tau_{Ksi})},$$

⁶ In section VII below (“Alternative Explanations”) we relax this assumption by replacing the plant-specific capital distortion with plant-specific factor shares.

$$(2.8) \quad L_{si} \propto \frac{A_{si}^{\sigma-1} (1 - \tau_{Ysi})^\sigma}{(1 + \tau_{Ksi})^{\alpha_s(\sigma-1)}}$$

$$(2.9) \quad Y_{si} \propto \frac{A_{si}^\sigma (1 - \tau_{Ysi})^\sigma}{(1 + \tau_{Ksi})^{\alpha_s \sigma}}$$

The allocation of resources across firms depends not only on firm TFP levels, but also on the output and capital distortions they face. To the extent resource allocation is driven by distortions rather than firm TFP, this will result in differences in the marginal revenue products of labor and capital across firms. The marginal revenue product of labor is proportional to revenue per worker:

$$(2.10) \quad MRPL_{si} \triangleq (1 - \alpha_s) \frac{\sigma - 1}{\sigma} \frac{P_{si} Y_{si}}{L_{si}} = w \frac{1}{1 - \tau_{Ysi}}.$$

The marginal revenue product of capital is proportional to the revenue-capital ratio:

$$(2.11) \quad MRPK_{si} \triangleq \alpha_s \frac{\sigma - 1}{\sigma} \frac{P_{si} Y_{si}}{K_{si}} = R \frac{1 + \tau_{Ksi}}{1 - \tau_{Ysi}}.$$

Intuitively, the after-tax marginal revenue products of capital and labor are equalized across firms. The before-tax marginal revenue products must be higher in firms that face disincentives, and can be lower in firms that benefit from subsidies.

We are now ready to derive an expression for aggregate TFP as a function of the misallocation of capital and labor. We first solve for the equilibrium allocation of resources across sectors:⁷

$$(2.12) \quad L_s \equiv \sum_{i=1}^{M_s} L_{si} = L \frac{(1 - \alpha_s) \theta_s / \overline{MRPL}_s}{\sum_{s'=1}^S (1 - \alpha_{s'}) \theta_{s'} / \overline{MRPL}_{s'}}$$

⁷ To derive K_s and L_s we proceed as follows. First, we derive the aggregate demand for capital and labor in a sector by aggregating the firm-level demands for the two factor inputs. We then combine the aggregate demand for the factor inputs in each sector with the allocation of total expenditure across sectors.

$$(2.13) \quad K_s \equiv \sum_{i=1}^S K_{si} = K \frac{\alpha_s \theta_s / \overline{MRPK}_s}{\sum_{s'=1}^S \alpha_{s'} \theta_{s'} / \overline{MRPK}_{s'}}.$$

Here, $\overline{MRPL}_s \propto \left(\sum_{s=1}^{M_s} \frac{1}{1 - \tau_{Ysi}} \frac{P_{si} Y_{si}}{P_s Y_s} \right)$ and $\overline{MRPK}_s \propto \left(\sum_{s=1}^{M_s} \frac{1 + \tau_{Ksi}}{1 - \tau_{Ysi}} \frac{P_{si} Y_{si}}{P_s Y_s} \right)$ denote the

weighted average of the value of the marginal product of labor and capital in a sector, and

$L \equiv \sum_{s=1}^S L_s$ and $K \equiv \sum_{s=1}^S K_s$ represent the aggregate supply of labor and capital. We

can then express aggregate output as a function of K_s , L_s , and industry TFP:⁸

$$(2.14) \quad Y = \prod_{s=1}^S \left(TFP_s \cdot K_s^{\alpha_s} \cdot L_s^{1-\alpha_s} \right)^{\theta_s}.$$

To determine the formula for industry productivity TFP_s , it is useful to show that firm-specific distortions can be measured by the firm's *revenue* productivity. It is typical in the productivity literature to have industry deflators but not plant-specific deflators.

Foster, Haltiwanger and Syverson (2008) stress that, when industry deflators are used, differences in plant-specific prices show up in the customary measure of plant TFP.

They stress the distinction between “physical productivity”, which they denote TFPQ, and “revenue productivity”, which they call TFPR. The use of a plant-specific deflator yields TFPQ, whereas using an industry deflator gives TFPR.

The distinction between physical and revenue productivity is vital for us too. We define these objects as follows:⁹

$$TFPQ_{si} \triangleq A_{si} = \frac{Y_{si}}{K_{si}^{\alpha_s} (wL_{si})^{1-\alpha_s}}$$

$$TFPR_{si} \triangleq P_{si} A_{si} = \frac{P_{si} Y_{si}}{K_{si}^{\alpha_s} (wL_{si})^{1-\alpha_s}}.$$

⁸ We combine the aggregate demand for capital and labor in a sector, the expression for the price of aggregate industry output, and the expression for the price of aggregate output.

⁹ To crudely control for differences in human capital we measure labor input as the wage bill, which we denote as the product of a common wage per unit of human capital w and effective labor input L_{si} .

In our simple model, TFPR does not vary across plants within an industry unless plants face capital and/or output distortions. In the absence of distortions, more capital and labor should be allocated to plants with higher TFPQ to the point where their higher output results in a lower price and the exact same TFPR as at smaller plants. Using (2.10) and (2.11), plant TFPR is proportional to a geometric average of the plant's marginal revenue products of capital and labor:¹⁰

$$TFPR_{si} \propto (MRPK_{si})^{\alpha_s} (MRPL_{si})^{1-\alpha_s} \propto \frac{(1 + \tau_{Ksi})^{\alpha_s}}{1 - \tau_{Ysi}}.$$

High plant TFPR is a sign that the plant confronts barriers that raise the plant's marginal products of capital and labor, rendering the plant smaller than optimal.

With the expression for TFPR in hand, we can express industry TFP as

$$(2.15) \quad TFP_s = \left(\sum_{i=1}^{M_s} \left\{ A_{si} \cdot \frac{\overline{TFPR}_s}{TFPR_{si}} \right\}^{\sigma-1} \right)^{\frac{1}{\sigma-1}},$$

where $\overline{TFPR}_s \propto (\overline{MRPK}_s)^{\alpha_s} (\overline{MRPL}_s)^{1-\alpha_s}$ is a geometric average of the average marginal revenue product of capital and labor in the sector.¹¹ If marginal products were equalized across plants, TFP would be $\bar{A}_s = \left(\sum_{i=1}^{M_s} A_{si}^{\sigma-1} \right)^{\frac{1}{\sigma-1}}$. Equation (2.15) is the key equation we use for our empirical estimates. Appendix A shows that we would arrive at a similar expression to (2.15) if we assumed a Lucas span-of-control model rather than monopolistic competition.

When A (\equiv TFPQ) and TFPR are jointly log-normally distributed, there is a simple closed form expression for aggregate TFP:

¹⁰ $TFPR_{si} = \frac{\sigma}{\sigma-1} \left(\frac{MRPK_{si}}{\alpha_s} \right)^{\alpha_s} \left(\frac{MRPL_{si}}{w(1-\alpha_s)} \right)^{1-\alpha_s} = \left(\frac{R}{\alpha_s} \right)^{\alpha_s} \left(\frac{1}{1-\alpha_s} \right)^{1-\alpha_s} \frac{(1 + \tau_{Ksi})^{\alpha_s}}{1 - \tau_{Ysi}}.$

¹¹ $\overline{TFPR}_s = \left[\frac{R}{\alpha_s} \sum_{i=1}^{M_s} \left(\frac{1 + \tau_{Ksi}}{1 - \tau_{Ysi}} \right) \cdot \left(\frac{P_{si} Y_{si}}{P_s Y_s} \right) \right]^{\alpha_s} \left[\frac{1}{1-\alpha_s} \sum_{i=1}^{M_s} \left(\frac{1}{1-\tau_{Ysi}} \right) \left(\frac{P_{si} Y_{si}}{P_s Y_s} \right) \right]^{1-\alpha_s}$

$$(2.16) \quad \log TFP_s = \frac{1}{\sigma-1} \log \left(\sum_{i=1}^{M_s} A_{si}^{\sigma-1} \right) - \frac{\sigma}{2} \text{var}(\log TFPR_{si}).$$

In this special case, the negative effect of distortions on aggregate TFP can be summarized by the variance of log TFPR. Intuitively, the extent of misallocation is worse when there is greater dispersion of marginal products.

We note several things about the effect of misallocation on aggregate TFP in this model. First, from (2.12) and (2.13), the shares of aggregate labor and capital devoted to a given sector are not affected by the extent of misallocation as long as the average marginal revenue of labor and capital do not change. Our assumption of a Cobb-Douglas aggregator (unit elastic demand) is responsible for this property (an industry that is 1% more efficient has a 1% lower price index and 1% higher demand, which can be accommodated without adding or shedding inputs). We relax this Cobb-Douglas assumption later to see how much it matters.

Second, we have conditioned on a fixed aggregate stock of capital. Because the rental rate rises with aggregate TFP, we would expect capital to respond to aggregate TFP (even with a fixed saving and investment rate). If we endogenize K by invoking a consumption Euler equation to pin down the long run rental rate R , the output elasticity with respect to aggregate TFP is $\frac{1}{1 - \sum_{s=1}^S \alpha_s \theta_s}$. Thus the effect of misallocation on output is increasing in the average capital share. This property is reminiscent of a one sector neoclassical growth model, wherein increases in TFP are amplified by capital accumulation so that the output elasticity with respect to TFP is $1/(1 - \alpha)$.

Third, we will assume that the number of firms in each industry is not affected by the extent of misallocation. In an Appendix available upon request, we show that the number of firms would be unaffected by the extent of misallocation in a model of endogenous entry in which entry costs take the form of a fixed amount of labor.¹²

¹² A critical assumption we make is that an entrant does not know its productivity or distortions *ex ante*. These are only known *ex post*, i.e., after expending entry costs. *Ex ante* a potential entrant knows only that they will receive a random draw from the existing joint distribution of distortions and productivity. We also follow Melitz (2003) and Restuccia and Rogerson (2008) in assuming exogenous exit.

III. Datasets for India, China and the U.S.

Our data for India are drawn from India's Annual Survey of Industries (ASI) conducted by the Indian government's Central Statistical Organisation (CSO). The ASI is a census of all registered manufacturing plants in India with more than 50 workers (100 if without power) and a random one-third sample of registered plants with more than 10 workers (20 if without power) but less than 50 (or 100) workers. For all calculations we apply a sampling weight so that our weighted sample reflects the population. The survey provides information on plant characteristics over the *fiscal* year (April of a given year through March of the following year). We use the ASI data from the 1987-1988 through 1994-1995 fiscal years. The raw data consists of around 40,000 plants in each year.

The variables in the ASI we use are the plant's industry (4-digit ISIC), labor compensation, value-added, age (based on reported birth year), and book value of the fixed capital stock. Specifically, the ASI reports the plant's total wage payments, bonus payments, and the imputed value of benefits. Our measure of labor compensation is the sum of wages, bonuses, and benefits. In addition, the ASI reports the book value of fixed capital at the beginning and end of the fiscal year net of depreciation. We take the average of the net book value of fixed capital at the beginning and end of the fiscal year as our measure of the plant's capital. We also have ownership information from the ASI, although the ownership classification does not distinguish between foreign owned and domestic plants.

Our data for Chinese plants are from Annual Surveys of Industrial Production from 1998 through 2005 conducted by the Chinese government's National Bureau of Statistics (NBS). The Annual Survey of Industrial Production is a census of all non-state plants with more than 5 million Yuan in revenue (about \$600,000) plus all state-owned plants. The raw data consists of over 100,000 plants in 1998 and grows to over 200,000 plants in 2005.

The information we use from the Chinese data are the plant's industry (again at the 4-digit level), age (again based on reported birth year), ownership, wage payments, value-added, export revenues, and capital stock. We define the capital stock as the book value of fixed capital net of depreciation. As for labor compensation, the Chinese data

only reports wage payments; it does not provide information on non-wage compensation. The median labor share in plant-level data is roughly 30%, which is significantly lower than the aggregate labor share in manufacturing reported in the Chinese input-output tables and the national accounts (roughly 50%). We therefore assume that non-wage benefits are a constant fraction of a plant's wage compensation, where the adjustment factor is calculated such that the sum of imputed benefits and wages across all plants equals 50% of aggregate value-added. We also have ownership status for the Chinese plants. Chinese manufacturing had been predominantly state-run or state-involved, but was principally private by the end of our sample.¹³

Our main source for U.S. data is the Census of Manufactures from 1977, 1982, 1987, 1992, and 1997 conducted by the U.S. Bureau of the Census. Befitting their name, the Census covers all manufacturing plants. We drop small plants with limited production data (Administrative Records), leaving over 160,000 plants in each year. The information we use from the U.S. Census are the plant's industry (again at the 4-digit level), labor compensation (wages and benefits), value-added, export revenues, and capital stock. We define the capital stock as the average of the book value of the plant's machinery and equipment and structures at the beginning and at the end of the year. The U.S. data does not provide information on plant age. We impute the plant's age by determining when the plant appears in the data for the first time.¹⁴

For our computations we set industry capital shares to those in the corresponding U.S. manufacturing industry. As a result, we drop non-manufacturing plants and plants in industries without a close counterpart in the U.S. We also trim the 1% tails of plant productivity and distortions in each country-year to make the results robust to outliers. Later we check robustness to adjusting the book values of capital for inflation.

¹³ Our data may understate the extent of privatization. Dollar and Wei (2007) conducted their own survey of Chinese firms in 2005, and found that 15% of all firms were officially classified as state-owned who had in fact been privatized.

¹⁴ For the plants in the Annual Survey of Manufactures (ASM), we use the annual data of the ASM (starting with the 1963 ASM) to identify the plant's birth year. For the plants that are not in the ASM, we assume the birth year is the year the plant first appears in the quincennial Census of Manufactures minus 3 years.

IV. Potential Gains from Reallocation

In order to calculate the effects of resource misallocation, we need to back out key parameters (industry output shares, industry capital shares, and the firm-specific distortions) from the data. We proceed as follows:

We set the rental price of capital (excluding distortions) to $R = 0.10$. We have in mind a 5% real interest rate and a 5% depreciation rate. The actual cost of capital faced by plant i in industry s is denoted $(1 + \tau_{Ksi})R$, so it differs from 10% if $\tau_{Ksi} \neq 0$. Because our hypothetical reforms collapse τ_{Ksi} to its average in each industry, the attendant efficiency gains do not depend on R . If we have set R incorrectly, it affects only the average capital distortion, not the liberalization experiment.

We set the elasticity of substitution between plant value added to $\sigma = 3$. The gains from liberalization are increasing in σ , as is explicit in (2.16), so we made this choice conservatively. Estimates of the substitutability of competing manufactures in the trade and industrial organization literatures typically range from 3 to 10 (e.g., Broda and Weinstein 2006, Hendel and Nevo 2006). Later we entertain the higher value of $\sigma = 5$ as a robustness check. Of course, the elasticity surely differs across goods (Broda and Weinstein report lower elasticities for more differentiated goods), so our single σ is a strong simplifying assumption.

As mentioned, we set the elasticity of output with respect to capital in each industry (α_s) to be one minus the labor share in the corresponding industry in the U.S. We do not set these elasticities based on labor shares in the Indian and Chinese data precisely because we think distortions are potentially important in China and India. We cannot separately identify the average capital distortion and the capital production elasticity in each industry. We adopt the U.S. shares as the benchmark because we presume the U.S. is comparatively undistorted (both across plants and, more to the point here, across industries). Our source for the U.S. shares is the NBER Productivity Database, which is based on the Census and Annual Surveys of Manufactures. One well-known issue with these data is that payments to labor omit fringe benefits and employer Social Security contributions. The CM/ASM manufacturing labor share is about 2/3 what it is in manufacturing according to the National Income and Product Accounts,

which incorporate non-wage forms of compensation. We therefore scale up each industry's CM/ASM labor share by 3/2 to arrive at the labor elasticity we assume for the corresponding U.S., Indian and Chinese industry.

One issue that arises when translating factor shares into production elasticities is the division of rents from markups in these differentiated good industries. Because we assume a modest σ of 3, these rents are large. We therefore assume these rents show up as payments to labor (managers) and capital (owners) pro rata in each industry. In this event our assumed value of σ has no impact on our production elasticities.

Based on the other parameters and the plant data, we infer the distortions and productivity for each plant in each country-year as follows:

$$(4.1) \quad 1 + \tau_{Ksi} = \frac{\alpha_s}{1 - \alpha_s} \frac{wL_{si}}{RK_{si}}$$

$$(4.2) \quad 1 - \tau_{Ysi} = \frac{\sigma}{\sigma - 1} \frac{wL_{si}}{(1 - \alpha_s) P_{si} Y_{si}}$$

$$(4.3) \quad A_{si} = \kappa_s \frac{(P_{si} Y_{si})^{\frac{\sigma}{\sigma-1}}}{K_{si}^{\alpha_s} L_{si}^{1-\alpha_s}},$$

Equation (4.1) says we infer the presence of a capital distortion when the ratio of labor compensation to the capital stock is high relative to what one would expect from the output elasticities with respect to capital and labor. Recall that a high labor distortion would show up as a low capital distortion. Similarly, expression (4.2) says we deduce an output distortion when labor's share is low compared to what one would think from the industry elasticity of output with respect to labor (and the adjustment for rents). A critical assumption embedded in (4.2) is that observed value added does *not* include any explicit output subsidies or taxes.

TFP in (4.3) warrants more explanation. First, the scalar is $\kappa_s = w^{1-\alpha_s} (P_s Y_s)^{-\frac{1}{\sigma-1}} / P_s$. Although we do not observe κ_s , relative productivities – and hence reallocation gains – are unaffected by setting $\kappa_s = 1$ for each industry s . Second and related, we do not

observe each plant's real output Y_{si} but rather its nominal output $P_{si}Y_{si}$. Plants with high real output, however, must have a lower price to explain why buyers would demand the higher output. We therefore raise $P_{si}Y_{si}$ to the power $\sigma/(\sigma-1)$ to arrive at Y_{si} . That is, we infer price vs. quantity from revenue and an assumed elasticity of demand. Equation (4.3) requires only our assumptions about technology and demand plus profit maximization; we need not assume anything about how inputs are determined. Third, for labor input we use the plant's wage bill rather than its employment to measure L_{si} . Earnings per worker may vary more across plants because of differences in hours worked and human capital per worker than because of worker rents. Still, as a later robustness check we measure L_{si} as employment.

Before calculating the gains from our hypothetical liberalization, we trim the 1% tails of $\log\left(\overline{TFPR}_{si} / \overline{TFPR}_s\right)$ and $\log\left(A_{si} / \bar{A}_s\right)$ across industries. That is, we pool all industries and trim the top and the bottom 1% of plants within each of the pools. We then recalculate wL_s , K_s , and P_sY_s as well as \overline{TFPR}_s and \bar{A}_s . At this stage we calculate the industry shares $\theta_s = P_sY_s / Y$.

Figure 1 plots the distribution of TFPQ, $\log\left(A_{si}M_s^{\frac{1}{\sigma-1}} / \bar{A}_s\right)$, for the latest year in each country: India in 1994, China in 2005, and the U.S. in 1997. There is manifestly more TFPQ dispersion in India than in China, but this could reflect the different sampling frames (small private plants are underrepresented in the Chinese survey). The U.S. and India samples are more comparable. The left-tail of TFPQ is far thicker in India than the U.S., consistent with policies favoring the survival of inefficient plants in India relative to the U.S. Table 1 shows that these patterns are consistent across years and several measures of dispersion of $\log(\text{TFPQ})$: the standard deviation, the 75th minus the 25th percentiles, and the 90th minus the 10th percentiles. The ratio of 75th to 25th percentiles of TFPQ in the latest year are 5.0 in India, 3.6 in China, and 3.2 in the U.S. (exponentials of the corresponding numbers in Table 2). For the U.S., our TFPQ differences are much larger than those documented by Foster, Haltiwanger and Syverson (2008) – they report a standard deviation of around 0.22 compared to ours of around 0.80. As we describe in

Appendix B, our measure of TFPQ should reflect the quality and variety of a plant’s products, not just its physical productivity. And our results cover all industries, whereas Foster et al. analyze a dozen industries specifically chosen because their products are homogenous.

Figure 2 plots the distribution of TFPR (specifically, $\log\left(\frac{TFPR_{si}}{\overline{TFPR_s}}\right)$) for the latest year in each country. There is clearly more dispersion of TFPR in India than in the U.S. Even China, despite not fully sampling small private establishments, exhibits notably greater TFPR dispersion than the U.S. Table 2 provides TFPR dispersion statistics for a number of country-years. The ratio of 75th to 25th percentiles of TFPR in the latest year are 2.2 in India, 2.3 in China, and 1.7 in the U.S. The ratios of 90th to 10th percentiles of TFPR are 5.0 in India, 4.9 in China and 3.3 in the U.S. These numbers are consistent with greater distortions in China and India than the U.S.¹⁵

Although it does not fit well into our monopolistically competitive framework, it is useful to ask how government-guaranteed monopoly power might show up in our measures of TFPQ and TFPR. Plants that charge high markups should evince higher TFPR levels. If they are also protected from entry of nearby competitors, they may also exhibit high TFPQ levels. Whereas we frame high TFPR plants as being held back by policy distortions, such plants may in fact be happily restricting their output. Still, such variation in TFPR is socially inefficient, and aggregate TFP would be higher if such plants expanded their output.

We next calculate “efficient” output in each country so we can compare it with actual output levels. If marginal products were equalized across plants in a given industry, then industry TFP would be $\bar{A}_s = \left(\sum_{i=1}^{M_s} A_{si}^{\sigma-1}\right)^{\frac{1}{\sigma-1}}$. For each industry, we calculate the ratio of actual TFP (2.15) to this efficient level of TFP, and then aggregate this ratio across sectors using our Cobb-Douglas aggregator (2.1):

¹⁵ Hallward-Driemeier, Jarossi and Sokoloff (2002) similarly report more TFP variation across plants in poorer East Asian nations (Indonesia and the Philippines vs. Thailand, Malaysia and South Korea).

$$(4.4) \quad \frac{Y}{Y_{efficient}} = \prod_{s=1}^S \left[\sum_{i=1}^{M_s} \left\{ \frac{A_{si}}{A_s} \frac{TFPR_s}{TFPR_{si}} \right\}^{\sigma-1} \right]^{\theta_s / (\sigma-1)} .$$

We freely admit this exercise heroically makes no allowance for measurement error or model misspecification. Such errors could lead us to overstate room for efficiency gains from better allocation. With these caveats firmly in mind, Table 3 provides % TFP gains in each country from fully equalizing TFPR across plants in each industry. We provide three years per country. Full liberalization, by this calculation, would boost aggregate manufacturing TFP by 86-115% in China, 100-128% in India, and around 30-43% in the U.S. If measurement and modeling errors are to explain these results, they clearly have to be much bigger in China and India than the U.S.

Figure 3 plots the “efficient” vs. actual size distribution of plants in the latest year. Size here is measured as plant value added. In all three countries the hypothetical efficient distribution is more dispersed than the actual one. In particular, there should be fewer mid-sized plants and more small and large plants. Table 4 shows how the size of initially big vs. small plants would change if TFPR were equalized in each country. The entries are un-weighted shares of plants. The rows are initial (actual) plant size quartiles, and the columns are bins of efficient plant size relative to actual size: 0-50% (the plant should shrink by a half or more), 50-100%, 100-200%, and 200+% (the plant should at least double in size). In China and India the most populous column is 0-50% for every initial size quartile. Although average output rises substantially, many plants of all sizes would shrink. Thus many state-favored behemoths in China and India would be downsized. Still, initially-large plants are less likely to shrink and more likely to expand in both China and India (a pattern much less pronounced in the U.S.). Thus TFPR increases with size more strongly in China and India than in the U.S.. The positive size-TFPR relation in India is consistent with Banerjee and Duflo’s (2005) contention that Indian policies constrain its most efficient producers and coddle its least efficient ones.

Although we expressed the distortions in terms of output (τ_{ysi}) and capital relative to labor (τ_{ksi}), in Appendix C we show these are equivalent to a particular combination

of labor (τ_{Lsi}^*) and capital (τ_{Ksi}^*) distortions. In the Appendix we report that more efficient (higher TFPQ) plants appear to face bigger distortions on both capital and labor.

In Table 5 we report the % TFP gains in China and India *relative to those in the U.S.* in 1997 (a conservative point of comparison as U.S. gains are largest in 1997). For China, hypothetically moving to “U.S. efficiency” might have boosted TFP by 50% in 1998, 37% in 2001, and 30% in 2005. Compared to the 1997 U.S. benchmark, Chinese allocative efficiency improved 15% (1.5/1.3) from 1998 to 2005, or 2.0% per year. For India, meanwhile, hypothetically moving to U.S. efficiency might have raised TFP around 40% in 1987 or 1991, and 59% in 1994. Thus we find no evidence of improving allocations in India over 1987 to 1994. The implied decline in allocative efficiency of 12%, or 1.8% per year from 1987 to 1994, is surprising given that many Indian reforms began in the late 1980s.

How do these implied TFP gains from reallocation compare to the actual TFP growth observed in China and India? For the latter, the closest estimates we could find are by Bosworth and Collins (2007). They report Chinese industry TFP growth of 6.2% per year from 1993-2004 and Indian industry TFP growth of 0.3% per year from 1978-1993. Thus our point estimate for China (2% per year) would suggest that perhaps 1/3 of its TFP growth could be attributed to better allocation of resources. For India, our evidence for worsening allocations might help explain its minimal TFP growth.

A related question is how our estimates of TFP losses from TFPR dispersion compare to actual, observed TFP differences between China/India and the U.S. We crudely estimate that U.S. manufacturing TFP in 1997 was 130% higher than China’s in 1998, and 160% higher than India’s in 1994.¹⁶ Therefore, our estimates suggest that resource misallocation might be responsible for roughly 49% ($\log(1.5)/\log(2.3)$) of the TFP gap between the U.S. and China and 35% ($\log(1.4)/\log(2.6)$) of the TFP gap between the U.S. and India.

¹⁶ We use the aggregate price of tradable goods between India and the U.S. in 1985 (from the benchmark data in the Penn World Tables) to deflate Indian prices to U.S. prices. Since we do not have price deflators for Chinese manufacturing, we use the Indian price of tradable goods to convert Chinese prices at market exchange rates to PPP prices. In addition, we assume that the capital-output ratio and the average level of human capital in the manufacturing sector is the same as that in the aggregate economy. The aggregate capital-output ratio is calculated from the Penn World Tables and the average level of human capital is calculated from average years of schooling (from Barro-Lee) assuming a 10% Mincerian return.

So far our calculations of hypothetical output gains from TFPR equalization assume a fixed aggregate capital stock. As discussed above, output gains are amplified when capital accumulates to keep the rental price of capital constant. In India's case the average capital share was 50% in 1994-1995, so the TFP gains are roughly squared. The same goes for China, as its average capital share was 49% in 2005. Thus a 30% TFP gain in China could yield a 67% long run gain in manufacturing output, whereas a 59% TFP gain in India could ultimately boost its manufacturing output by 153%.

We now provide a number of robustness checks on our baseline Table 5 calculations of hypothetical efficiency gains from liberalization in China and India relative to the U.S. We first adjust the book values of capital using a capital deflator for each country combined with the plant's age. We assume a plant's current investment rate applies to all previous years of its life so that we can infer the age distribution of its capital stock. The resulting "current market value" capital stocks suggest very similar room for TFP gains in China vs. the U.S. (29.8% vs. 30.5% baseline) and India vs. the U.S. (59.9% vs. 59.2% baseline).

In our baseline calculations we also measured plant labor input using its wage bill. Our logic was that wages per worker adjust for plant differences in hours worked per worker and worker skills. But wages could also reflect rent-sharing between the plant and its workers. If so, we might be understating differences in TFPR across plants because the most profitable plants have to pay higher wages. We therefore recalculate the gains from equalizing TFPR in China and India (relative to the U.S.) using simply employment as our measure of plant labor input. Surprisingly, the reallocation gains are smaller in both China (25.6% vs. 30.5% baseline) and India (57.4% vs. 59.2% baseline) when we measured labor input using employment. Thus wage differences appear to amplify TFPR differences rather than limit them.

We have assumed an elasticity of substitution within industries (σ) of 3, conservatively at the low end of empirical estimates. Our estimated gains are highly sensitive to this elasticity. China's hypothetical TFP gain in 2005 soars from 87% under $\sigma = 3$ to 184% with $\sigma = 5$, and India's in 1994 from 128% to 230%. These are gains from fully equalizing TFPR levels. Our intuition is as follows: when σ is higher, TFPR gaps

are closed more slowly in response to reallocation of inputs from low to high TFPR plants, enabling bigger gains from equalizing TFPR levels.

Our results are not nearly as sensitive to our assumption of a unitary elasticity of substitution between sectors. Cobb-Douglas aggregation across sectors means that TFPR equalization does not affect the allocation of inputs across sectors; the rise in a sector's productivity is exactly offset by the fall in its price index. Suppose instead that final output is a CES aggregate of sector outputs:

$$Y = \left(\sum_{s=1}^S \theta_s Y_s^{\frac{\phi-1}{\phi}} \right)^{\frac{\phi}{\phi-1}}$$

First consider the case wherein sector outputs are closer complements ($\phi = 0.5$). The gains from liberalization are modestly smaller in China (82% vs. 87% in 2005) and appreciably smaller in India (108% vs. 128% in 1994). The gains shrink because $\phi < 1$ means sectors with larger increases in productivity shed inputs. Next consider a case where sector outputs are more substitutable ($\phi = 2$). In this case, the gains from liberalization are modestly larger in China (90% vs. 87%) and larger in India (142% vs. 128%). When sector outputs are better substitutes, inputs are reallocated toward sectors with bigger productivity gains so that aggregate TFP increases more.

V. Measurement Error

Our potential efficiency gains could be a figment of greater measurement error in Chinese and Indian data than in the U.S. data. We cannot rule out arbitrary measurement error, but we can we try to gauge whether our results can be attributable to specific forms of measurement error. One form is simply recording errors that create extreme outliers. For our baseline estimates (Table 5) we trimmed the 1% tails of TFPR (actually, in the output and capital distortions separately) and TFPQ – up to 6% of observations. When we trim 2% tails (up to 12% of observations) the hypothetical TFP gains fall from 87% to 69% for China in 2005, and from 128% to 106% for India in 1994. Thus, measurement

error in the remaining 1% tails could well be important, but does not come close to accounting for the big gains from equalizing TFPR.

Of course, measurement error could be important in the interior of the TFPR distribution too. Suppose measurement error is classical in the sense of being orthogonal to the truth and to other reported variables. Then we would not expect plant TFPR to be related to plant ownership. Table 6 shows that, in fact, TFPR is systematically related to ownership in mostly reassuring ways in China and India. The table presents results of regressing TFPR and TFPQ (relative to industry means) on ownership type in China and India. All years are pooled and year fixed effects are included. The omitted group for China is privately-owned domestic plants, whereas in India it is privately-owned plants because we lack information on foreign ownership in India. In China, state-owned plants exhibit 41% lower TFPR, as if they received subsidies to continue operating despite low profitability.¹⁷ Perhaps surprisingly, collectively-owned (part private, part local government) plants have 11% higher TFPR. Foreign-owned plants have 23% higher TFPQ on average, but 13% lower TFPR. The latter could reflect better access to credit or preferential treatment in export processing zones. Consistent with this interpretation, *exporting* plants have 46% higher TFPQ but 14% lower TFPR. In the U.S., exporters have a similar TFPQ advantage (50%) but display higher rather than lower TFPR (+6% on average).¹⁸

In India, all types of plants with public involvement exhibit lower TFPR: 29% lower for plants owned by the central government, 8% lower for those owned by local governments, and 16% lower for joint public-private plants. Public involvement also goes along with 40-70% higher TFPQ, although this might reflect monopoly rights that guarantee demand.

We next look at the correlation of TFPR with plant exit. One would expect true TFPR to be lower for exiters. If TFPR is measured with more error in China and India, the coefficient from a regression of plant exit on TFPR should be biased downwards. Table 7 shows that lower TFPR is associated with a higher probability of plant exit in all

¹⁷ Dollar and Wei (2007) likewise find lower productivity at state-owned firms in China.

¹⁸ The high TFPQ of exporters could reflect the “demand shock” coming from accessing foreign markets, rather than just physical productivity.

three countries. A one log point decrease in TFPR is associated with a 1.1% higher exit probability in China and a 1.9% higher exit probability in India, compared to 1.1% higher exit probability in the U.S. Low TFPR firms disproportionately exit in China and India, suggesting TFPR is a strong signal of profitability. Of course, government subsidies might allow many unprofitable plants to continue rather than exit. But that is not what Table 7 shows, perhaps because of the reforms underway in both countries.

We can also look at the correlation of TFPQ with exit, as measurement error in TFPR should also show up as measurement error in TFPQ. (Recall that $\log \text{TFPR}$ is $\log \text{revenues} - \log \text{inputs}$ and $\log \text{TFPQ}$ is $\frac{\sigma}{\sigma-1} \log \text{revenues} - \log \text{inputs}$.) Table 7 shows that lower TFPQ is associated with higher exit probabilities, with a stronger relationship in China and a weaker relationship in India when compared with the U.S. If the true relationship between TFPQ and plant exit is the same in the three countries, then this evidence suggests *less* measurement error in China, but more measurement error in India when compared to the U.S.

We can also directly assess the extent of classical measurement error in plant revenue and inputs. If the % errors in revenue and inputs are uncorrelated with each other, and true elasticities are the same in all countries, then we expect lower coefficients in China and India when we regress log revenue on log inputs or vice versa. We present such regressions in Table 8, pooling all years for a given country and measuring variables relative to industry means. The elasticity of inputs with respect to revenue is 0.96 in India and 0.98 in China, vs. 1.01 in the U.S. These coefficients suggest greater classical measurement error might be adding 5% to the variance of log revenue in India and 3% to the variance in China. The elasticity of revenue with respect to inputs is 0.82 in China, 0.90 in India, and 0.82 in the U.S. These coefficients suggest classical measurement error has the same effect on the variance of log inputs in China as in the U.S., but actually lowers the variance in India by 10% relative to the U.S. Putting the two-way regressions together, greater classical measurement could contribute to the higher variance of TFPR in China, but not in India. This evidence is not conclusive because the true elasticities could be lower in China and India than the U.S., but it does provide mixed evidence on whether there is greater measurement error in China and India relative to the U.S.

Suppose further that, for a given plant, measurement error is less serially correlated than true revenue and inputs, and that the true serial correlations are the same for all countries. Then we would expect the growth rates of revenue and inputs to vary more across plants in China and India than the U.S. Table 9 presents the relevant statistics.¹⁹ Input growth actually varies much less across plants in China and India than the U.S. Revenue growth, however, varies a lot more in China and India than the U.S. So the growth rates, too, provide mixed evidence on whether TFPR is noisier in China and India. Of course, true dispersion of input growth could be lower in China and India.

Finally, if measurement error is less persistent than true variables, then “instrumenting” with lagged variables should shrink efficiency gains more in China and India than in the U.S. The TFP gain from fully equalizing TFPR levels falls from 87% under “OLS” to 72% under “IV” in 2005 China, from 127% to 108% in 1994 India, and from 43% to 26% in the 1997 U.S. By this metric, measurement error accounts for a bigger fraction of the gains in the U.S. than in China or India. Of course, it could instead be that measurement error is more persistent than true TFPR.

To recap, the statistics in this subsection are inconclusive. They do not provide clear evidence that the signal-to-noise ratio for TFPR is higher in the U.S. than in China and India, but neither do they entirely rule out the possibility. In addition, we cannot rule out non-classical measurement error across plants as the source of greater TFPR dispersion in China and India.

VI. Policies and Misallocation

If TFPR dispersion is real rather than a byproduct of measurement error, then we should be able to relate TFPR gaps to explicit government policies. In this subsection we relate TFPR dispersion in China to state ownership of plants, and TFPR dispersion in India to licensing and size restrictions.

Table 10 gives the percent of plants that are state-owned in China: 29% in 1998, 19% in 2001, and 8% in 2005. (In India the share of state-affiliated plants fell less

¹⁹ For this and all other U.S. calculations requiring a panel, we use the Annual Survey of Manufactures rather than just the Census of Manufactures. We measure input growth as the growth rate of $K_{si}^\alpha L_{si}^{1-\alpha}$.

dramatically, from 12% of plants in 1987 to 8% in 1994.) Now, in Table 6 we documented roughly 40% lower TFPR at state-owned plants vs. private domestic plants in China. This raises the question of how much of China's TFPR dispersion can be accounted for by state-ownership. In Table 11 we examine this relationship across the 400 or so 4-digit industries in China. We regress the industry variance of log TFPR on the industry share of plants owned by the state. The relationship is positive and significant in both 1998 and 2001, with a one percent higher state share of plants associated with about 0.7 percent higher TFPR dispersion. The relationship is no longer significant by 2005, and Figure 4 shows why. State-owned plants have much higher relative TFPR in 2005 than in 2001; some of this is due to exit of the least productive state plants, but the figure shows a sizable increase in the relative TFPR of surviving plants as well.²⁰ When we equalize TFPR only within ownership categories, the gains are 8.2% lower in 1998 and 2.4% lower in 2005. Therefore, of the 15% reduction in potential gains from reallocation in China from 1998 to 2005, we calculate that 39% (5.8/15.0) comes from the shrinking TFPR gap between SOEs and other plants.

In India, misallocation within industries has often been attributed to licensing and size restrictions, among other government policies (see, for example, Kochar et al. 2006). These distortions may prevent efficient plants from achieving optimal scale and keep inefficient plants from contracting or exiting. The Indian government de-licensed many industries in 1980 (about 40% of industries by value added share) and in 1991 (about 42% of industries by value added share).²¹ India lifted its size restrictions much more recently (1997-2005), which unfortunately we are unable to analyze because our data ends in 1994-95. Across industries during our sample, the mean share of industry value added subject to size restrictions was 21% with a standard deviation of 16%.²²

In Table 12 we relate the dispersion of industry TFPR to whether the industry was de-licensed in 1991 and to whether the industry faced size restrictions. The first column shows that industries de-licensed in 1991 exhibited less dispersion of TFPR, but *not* in particular for 1991 onward. It is as if licensed industries had lower TFPR dispersion

²⁰ Among state-owned plants in 1998, those privatized by 2005 had 11% higher TFPR (and 26% higher TFPQ) than state-owned plants exiting by 2005.

²¹ Based on three-digit data in Aghion et al. (2008).

²² The list of industries subject to size restrictions is from Mohan (2002)

despite their licensing restrictions, and the de-licensing did not affect this. The reason may be that many of the de-licensed industries were still subject to size restrictions. The second column of Table 12 indicates that the variance of log TFPR is greater within industries subject to size restrictions. We interact de-licensing with size restrictions and years after 1991 in the third column, and find that industries de-licensed in 1991 who face size restrictions do indeed display more TFPR dispersion from 1991 onward. De-licensed industries not facing size restrictions did exhibit lower TFPR from 1991, but not significantly so.

India's licensing restrictions might particularly restrict the ability of plants to acquire inputs when their efficiency rises. If so, then we would expect plants with rising TFPQ to have higher TFPR, but more so before de-licensing than afterward. For Indian industries de-licensed in 1991, Figure 5 plots average log TFPR against percentiles of plant TFPQ growth, with both variables relative to industry means. As predicted, the relationship is positive but notably flatter after de-licensing. Whereas TFPR differed by 1.2 log points across 90th vs. 10th percentile TFPQ growth before de-licensing, it differed by 0.6 log points after de-licensing.

We find little evidence that TFPR dispersion is correlated with measures of geography, industry concentration, and (in India) labor market regulation. Average TFPR levels differ modestly (within 10%) across Chinese provinces and Indian states, so that the overwhelming majority of our TFPR differences are within industry-regions. Within industry-regions we tried without success to relate TFPR dispersion to industry concentration using a Herfindahl index. For India we experimented with an index of labor regulation for each industry, calculated as a weighted average of the cumulative index of labor regulation in Besley and Burgess (2004) in each state, with weights equal to value added shares of each industry in each state. This index was not significantly related to the variance of log TFPR across industries, whether interacting and/or controlling for de-licensing and 1991 onward.

VII. Alternative Explanations

We now entertain alternative explanations for TFPR dispersion besides policy distortions and measurement error. Specifically, we briefly examine varying markups

with plant size, adjustment costs, unobserved investments (such as R&D), and varying capital elasticities within industries. All of these surely contribute to TFPR dispersion in all three countries, but our question is whether they might explain the *wider* TFPR dispersion in China and India than in the U.S.

Varying markups with plant size

Our CES aggregation of plant value added within industries implies that all goods have the same markup within industries (not to mention across industries). Yet markups might be higher for bigger plants, and there may be greater size dispersion in our Chinese and Indian data than in the U.S. data. Markups are distortions too, of course, but their dispersion may not wholly reflect policy differences between the countries. Melitz and Ottaviano (2008) analyze the case of linear demand, under which the elasticity of demand is falling (and the markup increasing) with size. Figure 6 shows why we did not go this route. Whereas TFPR is strongly increasing in percentiles of plant size (value added) in India and mostly increasing in plant size in China, if anything TFPR decreases with plant size in the U.S. If linear demand applied everywhere then TFPR should increase with size in the U.S. too. The fact that China and India differ not only quantitatively but qualitatively from the U.S. suggests more than just amplification of usual U.S. forces.

Adjustment costs

Young plants might have higher TFPR on average due to adjustment costs. If Chinese and Indian plants also differ in age more than U.S. plants do, differences in adjustment costs by age could contribute to wider TFPR dispersion in China and India. Figure 7 plots average log TFPR (relative to industry means) by percentile of plant age in each country. TFPR steadily increases with plant age in India, contrary to this story. In China TFPR rises through the youngest decile, then is flat or mildly decreasing in the inter-decile range before falling for the oldest decile. Only the U.S. exhibits the predicted pattern of steadily falling TFPR with age.

More generally, growing plants might have higher TFPR than shrinking plants due to adjustment costs. And input growth rates may vary more in China and India, due to their reforms, than in the U.S. with its more stable policy environment. Figure 8 plots

average TFPR by percentile of plant input growth. TFPR is increasing in input growth in all three countries, as predicted. But the U.S. exhibits more variation in TFPR associated with input growth than do China and India. Related, recall from Table 9 that input growth actually varies more across U.S. plants than across plants in China or India. The U.S. displays more churning, so if anything should have more TFPR variation due to convex adjustment costs in input growth.²³

Input growth may vary less in China and India because its plants are hit with less volatile idiosyncratic shocks and/or because they face higher adjustment costs. Cooper and Haltiwanger (2006) estimate idiosyncratic profitability shocks in a panel of U.S. plants based on regressions of log profits (actually log revenue minus (roughly) 0.5 log capital) on its lagged value and year dummies. When we repeat their estimation for all three countries, we obtain similar estimates for the U.S. (serial correlation 0.81, innovation standard deviation 0.56), China (0.79 and 0.59) and India (0.84 and 0.57). The overall standard deviation is 1% higher for China than the U.S. and 10% higher for India than the U.S. By comparison, in Table 2 the standard deviations of TFPR are over 50% higher for China and India than the U.S. Thus it would seem that plants in China and India face greater barriers to reallocation as opposed to bigger shocks with the same costs of reallocation.

Figure 7 related *average* TFPR to plant age. A related hypothesis is that young (or small) plants display greater dispersion of TFPR. If plants in China/India are younger or smaller than U.S. plants, therefore, then one might expect them to display more variable TFPR. Table 13 provides the age of the 25th, 50th, and 75th percentile plants in each country. Chinese plants (median age 5 years) are younger than U.S. plants (median age 10 years), but Indian plants are older (median age 12 years). Figure 9 plots the size (employment) distribution of plants in all three countries. Indian plants (median size 33 employees) are smaller than U.S. plants (median size 47 employees), but Chinese plants (median size 160 employees) are much larger than U.S. plants. When we split plants into quartiles of size and age (respectively) and equalize TFPR only within quartiles, the gains

²³ Another interpretation of Figure 8 is in terms of whether inputs are being reallocated to plants with higher TFPR. The answer is yes in all three countries, but more so in the U.S. This is consistent with more efficient resource allocation in the U.S.

are about 5% lower for both China and India. Thus variation in TFPR by size and age explains only a modest amount of the overall dispersion in TFPR.

Unobserved investments

Low TFPR might reflect learning by doing or other unobserved investments (R&D, building a customer base) rather than distortions. If so, then we expect low TFPR plants to exhibit high subsequent TFPQ growth. Figure 10 displays precisely this pattern in the U.S., but the opposite pattern in China and India. Thus it is far from obvious that unobserved plant investments vary more in China and India than in the U.S. If TFPQ growth does proxy for unobserved investments, then Figure 10 suggests such investments may mitigate TFPR differences in China and India.

Perhaps related, TFPR differences are more transitory in the U.S. than in China and India (see the “IV” results discussed near the end of section V). U.S. TFPR differences may largely reflect temporary differences in investments and adjustment costs, whereas TFPR differences in China and India may reflect more persistent, perhaps policy-related gaps that are not as reliably closed with subsequent input reallocation and TFPQ growth.

Varying capital shares within industries

Our baseline estimates in Table 5 assumed the same capital elasticity for all plants within a 4-digit industry. We inferred capital-labor distortions from variation in capital-labor ratios within industries. At the other extreme, one could attribute all variation in capital-labor ratios within industries to plant-specific capital shares. We do so and recalculate the TFP gains for China and India relative to the U.S. Evidently the majority of the baseline gains in China and India stem from output distortions. With plant-specific capital shares, TFP gains are still 23-45% (vs. 30-50% baseline) for China and 32-39% (vs. 40-60% baseline) for India.

VIII. Conclusion

A long stream of papers has stressed that misallocation of inputs across firms can reduce aggregate TFP in a country. We used micro data on manufacturing plants to investigate the possible role of such misallocation in China (1998-2005) and India (1987-1994) compared to the U.S. (1977, 1987, 1997). Viewing the data through the prism of a standard monopolistic competition model, we estimated differences in marginal products of labor and capital across plants within narrowly-defined industries. We found much bigger gaps in China and India than in the U.S. We then entertained a counterfactual move by China and India to the U.S. dispersion of marginal products. We found that this would boost TFP by 30-50% in China and by 40-60% in India. Room for reallocation gains shrank about 2% per year from 1998-2005 in China, as if reforms there reaped some of the gains. In India, despite reforms in the early 1990s, we report evidence of rising misallocation from 1991 to 1994.

Our results require many caveats. There could well be greater measurement error in the Chinese and Indian data than in the U.S. data. The static monopolistic competition model we deploy could be a particularly bad approximation for manufacturing in China and India in the wake of reforms there. Although we provided reassuring evidence on each of these concerns, our investigation was very much a first pass. In addition to investigating these issues more fully, future work could try to relate differences in plant productivity to observable policy distortions much more than we have.

Appendix A: Lucas Span-of-Control Version

In the main text we modeled manufacturing plants as monopolistic competitors, and related the elasticity of substitution between varieties to a large empirical literature. But many modelers, such as Restuccia and Rogerson (2008), follow Lucas (1978) in positing diminishing returns in production rather than utility. Here we show how the two formulations are isomorphic for aggregate TFP for a given number of plants and aggregate labor input.

Suppose labor is the sole input and there is a single sector. The equations for aggregate output, firm output, and firm profits for each variety are:

$$Y = \sum_{i=1}^M Y_i$$

$$Y_i = A_i L_i^\gamma$$

$$\pi_i = (1 - \tau_i) P Y_i - w L_i.$$

Returns to scale equal γ and P is the price of homogeneous output. TFP (= Y/L here) is:

$$TFP = \left(\sum_{i=1}^M \left\{ TFPQ_i \left(\frac{TFPR}{TFPR_i} \right)^{\frac{1}{1-\gamma}} \right\} \right)^{1-\gamma} / L^{1-\gamma}.$$

Here $TFPQ_i = A_i$ and $TFPR_i = 1 / (1 - \tau_i)$. This is same as our expression in the main text, except for two differences. First, $1 / (1 - \gamma)$ takes the place of $(\sigma - 1)$. Diminishing returns in production ($\gamma < 1$) play the same role as diminishing returns in utility ($\sigma < 1$). Second, aggregate TFP is now decreasing in aggregate labor input. If the number of plants is proportional to labor input, then such aggregate decreasing returns disappear. Of course, a variety benefit would then exist in the CES formulation. In terms of our calibration, our conservative choice of $\sigma = 3$ corresponds to $\gamma = 0.5$. This is quite low, even compared to studies such as Atkeson and Kehoe (2005), who chose $\gamma \geq 0.8$ based on diminishing returns in both production and utility.

Appendix B: Generalizing TFPQ for Quality and Variety

Here we sketch how our measure of TFPQ should capture not only process efficiency but also firm differences in quality and variety (equivalently, idiosyncratic demand). For simplicity, suppose labor is the sole input and there is a single sector. The equations for aggregate output, firm output, and firm profits for each variety are:

$$Y = \left[\sum_{i=1}^M N_i (Q_i Y_i / N_i)^{\frac{\sigma-1}{\sigma}} \right]^{\frac{\sigma}{\sigma-1}}$$

$$Y_i = A_i L_i$$

$$\pi_i = (1 - \tau_i) P_i Y_i - w L_i.$$

Here N_i is the number of symmetric varieties the firm produces, Q_i is the symmetric quality of each of its varieties, A_i is its process efficiency, Y_i / N_i is the symmetric quantity it produces of each variety, and P_i is the symmetric price of each variety. For this economy, our method of measuring TFPQ yields

$$TFPQ_i = \frac{(P_i Y_i)^{\frac{\sigma}{\sigma-1}} / L_i}{Y^{\frac{1}{\sigma-1}} P^{\frac{\sigma}{\sigma-1}}} = A_i Q_i N_i^{\frac{1}{\sigma-1}}.$$

Measured TFPQ is a composite of process efficiency and idiosyncratic demand terms coming from quality and variety. Aggregate TFP (= Y/L here) is identical to the case in which firms vary only in process efficiency, only with the above measure of TFPQ:

$$TFP = \overline{TFPQ} = \left(\sum_{i=1}^M \left\{ TFPQ_i \left(\frac{\overline{TFPR}}{TFPR_i} \right) \right\}^{\sigma-1} \right)^{\frac{1}{\sigma-1}}.$$

TFPR is as in the main text, only here it reduces to the single distortion, $TFPR_i = \frac{1}{1 - \tau_i}$.

Note that aggregate TFP (effective output per worker) is also synonymous with welfare.

Appendix C: Labor and Capital Distortions

In the main text we estimated distortions to output (τ_{Ysi}) and to capital *relative* to labor (τ_{Ksi}), respectively. An observationally equivalent characterization is in terms of distortions to the *absolute* levels of capital and labor. Denote level distortions as τ_{Lsi}^* and τ_{Ksi}^* , and profits as $\pi_{si} = P_{si}Y_{si} - (1 + \tau_{Lsi}^*)wL_{si} - (1 + \tau_{Ksi}^*)RK_{si}$. The firm's first order conditions are identical to those with $\{\tau_{Ysi}, \tau_{Ksi}\}$ assuming $1 - \tau_{Ysi} = \frac{1}{1 + \tau_{Lsi}^*}$ and

$$1 + \tau_{Ksi} = \frac{1 + \tau_{Ksi}^*}{1 + \tau_{Lsi}^*}. \text{ Sectoral TFP is identical under these conditions as well.}$$

We denote deviations of plant variables from industry weighted means as

$$\Delta A_{si} = \ln \frac{A_{si}}{A_s}, \Delta \tau_{Lsi}^* = \ln \frac{1 + \tau_{Lsi}^*}{1 + \bar{\tau}_{Ls}^*}, \Delta \tau_{Ksi}^* = \ln \frac{1 + \tau_{Ksi}^*}{1 + \bar{\tau}_{Ks}^*}, \text{ and } \Delta L_{si} = \ln \frac{wL_{si}}{\sum_{i=1}^{M_s} wL_{si} / M_s}. \text{ For the}$$

latest years in China and India, the correlation matrices of these variables are:

	China 2005			India 1994		
	ΔA_{si}	$\Delta \tau_{Lsi}^*$	$\Delta \tau_{Ksi}^*$	ΔA_{si}	$\Delta \tau_{Lsi}^*$	$\Delta \tau_{Ksi}^*$
ΔL_{si}	0.518	-0.202	-0.074	0.690	0.010	-0.038
$\Delta \tau_{Lsi}^*$	0.532	1	0.201	0.538	1	0.004
$\Delta \tau_{Ksi}^*$	0.592	0.201	1	0.398	0.004	1

Not surprisingly, plants with high TFPQ tend to have high labor input. More interestingly, plants with high TFPQ typically face higher “taxes” on both capital and labor. The distortions discourage labor input, but not strongly – because, again, the distortions tend to be high when TFPQ would dictate high labor input. Labor and capital wedges are positively correlated across plants, but only modestly so.

Here we can entertain the thought experiment of eliminating variation in the capital or labor distortion individually. For the latest year in China, the TFP gains from eliminating the capital (labor) distortion alone are 60% (24%) compared to 87% to eliminating both distortions. In India, the gains from eliminating the capital (labor) distortion alone are 78% (33%) compared to 128% from eliminating both distortions.

Table 1**Dispersion of TFPQ**

90-10	1.04	1.01	1.19

Notes: For plant i in industry s , $TFPR_{si} \equiv \frac{P_{si}Y_{si}}{K_{si}^{\alpha_s}(w_{si}L_{si})^{1-\alpha_s}}$. Statistics are for deviations of

$\log(TFPR)$ from industry means. S.D. = standard deviation, 75-25 is the difference between the 75th and 25th percentiles, and 90-10 the 90th vs. 10th percentiles. Industries are weighted by their value added shares. Number of plants is the same as in Table 1.

Table 3

TFP Gains from Equalizing TFPR Within Industries

China

	1998	2001	2005
%	115.1	95.8	86.6

India

	1987	1991	1994
%	100.4	102.1	127.5

U.S.

	1977	1987	1997
%	36.1	30.7	42.9

Notes: Entries are $100(Y_{efficient} / Y - 1)$ where $\frac{Y}{Y_{efficient}} = \prod_{s=1}^S \left[\sum_{i=1}^{M_s} \left\{ \frac{A_{si}}{A_s} \frac{\overline{TFPR}_s}{TFPR_{si}} \right\}^{\sigma-1} \right]^{\theta_s / (\sigma-1)}$

and $TFPR_{si} \equiv \frac{P_{si} Y_{si}}{K_{si}^{\alpha_s} (w_{si} L_{si})^{1-\alpha_s}}$.

Table 4**% of Plants, Actual Size vs. Efficient Size****China 2005**

	0-50%	50-100%	100-200%	200+%
Top Size Quartile	7.0	6.1	5.4	6.6
2nd Quartile	7.3	5.9	5.3	6.6
3rd Quartile	8.5	6.0	5.2	5.4
Bottom Quartile	10.5	5.9	4.5	4.2

India 1994

	0-50%	50-100%	100-200%	200+%
Top Size Quartile	8.7	4.7	4.6	7.1
2nd Quartile	10.7	4.6	4.1	5.7
3rd Quartile	11.4	5.0	4.0	4.7
Bottom Quartile	13.8	3.9	3.3	3.8

U.S. 1997

	0-50%	50-100%	100-200%	200+%
Top Size Quartile	4.4	10.0	6.7	3.9
2nd Quartile	4.4	9.6	5.8	5.1
3rd Quartile	4.5	9.8	5.4	5.4
Bottom Quartile	4.7	12.0	4.3	4.1

Notes: In each country-year, plants are put into quartiles based on their actual value added, with an equal number of plants in each quartile. The hypothetically efficient level of each plant's output is then calculated, assuming distortions are removed so that TFPR levels are equalized within industries. The entries above show the % of plants with efficient/actual output levels in the four bins 0-50% (efficient output less than half actual output), 50-100%, 100-200%, and 200%+ (efficient output more than double actual output). The rows add up to 25%, and the rows and columns together to 100%.

Table 5

TFP Gains from Equalizing TFPR *relative to 1997 U.S. Gains*

<u>China</u>	1998	2001	2005
%	50.5	37.0	30.5
<u>India</u>	1987	1991	1994
%	40.2	41.4	59.2

Notes: For each country-year, we calculated $Y_{efficient}/Y$ using

$$\frac{Y}{Y_{efficient}} = \prod_{s=1}^S \left[\sum_{i=1}^{M_s} \left\{ \frac{A_{si} \overline{TFPR}_s}{\overline{A}_s TFPR_{si}} \right\}^{\sigma-1} \right]^{\theta_s / (\sigma-1)} \quad \text{and} \quad TFPR_{si} \equiv \frac{P_{si} Y_{si}}{K_{si}^{\alpha_s} (w_{si} L_{si})^{1-\alpha_s}}.$$

We then took the ratio of $Y_{efficient}/Y$ to the U.S. ratio in 1997, subtracted 1, and multiplied by 100 to yield the entries above.

Table 6**TFP by ownership**

<u>China</u>	TFPR	TFPQ
State	-0.415 (0.023)	-0.144 (0.090)
Collective	0.114 (0.010)	0.047 (0.013)
Foreign	-0.129 (0.024)	0.228 (0.040)
<u>India</u>	TFPR	TFPQ
State (Central)	-0.285 (0.082)	0.717 (0.295)
State (Local)	-0.081 (0.063)	0.425 (0.103)
Joint Public/Private	-0.162 (0.037)	0.671 (0.085)

Notes: The dependent variable is the deviation of log TFPR or log TFPQ from the industry mean. The independent variables for China are dummies for state-owned plants, collective-owned plants (plants jointly owned by local governments and private parties), and foreign-owned plants. The omitted group is domestic private plants. The independent variables for India are dummies for a plant owned by the central government, a plant owned by a local government, and a plant jointly owned by the government (either central or local) and by private individuals. The omitted group is a privately owned plant (both domestic and foreign). Regressions are weighted least squares with industry value added shares as weights. Entries are the dummy coefficients, with standard errors in parentheses. Results are pooled for all years.

Table 7

Regressions of Exit on TFPR, TFPQ

China

Exit on TFPR	-0.011 (0.003)
Exit on TFPQ	-0.050 (0.002)

India

Exit on TFPR	-0.019 (0.005)
Exit on TFPQ	-0.027 (0.004)

U.S.

Exit on TFPR	-0.011 (0.003)
Exit on TFPQ	-0.039 (0.002)

Notes: The dependent variables are dummies for exiting plants. The independent variables are the deviation of log(TFPR) or log(TFPQ) from the industry mean. Regressions are weighted least squares with the weights being industry value added shares. Entries above are the coefficients on log(TFPR) or log(TFPQ), with S.E. referring to their standard errors. Regressions also include a quartic function of plant age. Results are pooled for all years.

Table 8

Regressions of Inputs on Revenue, Revenue on Inputs

	China	India	U.S.
Inputs on Revenue	0.98	0.96	1.01
Revenue on Inputs	0.82	0.90	0.82

Notes: Entries are the coefficients from regressions of $\log P_{si}Y_{si}$ on $\log K_{si}^{\alpha_s} (wL_{si})^{1-\alpha_s}$ (revenue on inputs) and $\log K_{si}^{\alpha_s} (wL_{si})^{1-\alpha_s}$ on $\log P_{si}Y_{si}$ (inputs on revenue). All variables are measured relative to the industry mean, with industries weighted by value-added shares. Results are pooled for all years.

Table 9

Dispersion of Input and Revenue Growth

<u>China</u>	Inputs	Revenue
S.D.	0.45	1.00
75-25	0.34	0.93
<u>India</u>	Inputs	Revenue
S.D.	0.28	0.70
75-25	0.24	0.60
<u>U.S.</u>	Inputs	Revenue
S.D.	0.68	0.43
75-25	0.43	0.32

Notes: Entries are the standard deviation (S.D.) and inter-quartile range (75-25) of $d \log P_{si} Y_{si}$ and $d \log K_{si}^{\alpha_s} (w_{si} L_{si})^{1-\alpha_s}$. All variables are measured relative to the industry mean, and with industries weighted by their value added shares. Entries are pooled for all years.

Table 10**Ownership of Indian and Chinese Plants****China**

	1998	2001	2005
Private Domestic	15.9	37.4	62.5

Private	87.7	88.4	92.4
State (Central Gov.)	3.3	3.3	2.4
State (Local Gov.)	3.9	3.0	2.8
Joint Public/Private	5.1	5.4	2.4

Notes: Entries are the percentage of the number of plants in each ownership category in the sector, where each sector is weighted by the value-added share of the sector. Each column adds to 100.

Table 11

**Regressions of Sector TFPR Dispersion on
State Ownership in China**

	1998	2001	2005	1998-2005
State Ownership Share	0.766 (0.165)	0.659 (0.153)	0.025 (0.213)	0.300 (0.080)
Year F.E.	NO	NO	NO	YES
Sector F.E.	NO	NO	NO	YES
N	406	403	407	3,237

Note: Entries are coefficients from regressions of the variance of log TFPR in sector s on the variance in sector s of an indicator variable for a state owned plant. All regressions are weighted by the value-added weights of the sector. Standard errors are clustered by sector in column 4.

Table 12

**Regression of Sector TFPR Dispersion
on De-licensing and Size Restrictions in India**

	(1)	(2)	(3)
De-licensed 1991	-0.298 (0.117)		-0.298 (-.117)
De-licensed 1991 x post 1991	0.032 (0.036)		-0.056 (0.040)
Size restriction		0.368 (0.173)	
De-licensed 1991 x post 1991 x size restriction			0.415 (0.120)

Notes: The dependent variable is the variance of log TFPR in sector s in year t . Entries are coefficients on the following independent variables: 1) **de-licensed 1991**: indicator for whether industry was de-licensed in 1991; 2) **de-licensed 1991 x post 1991**: product of an indicator for an industry de-licensed in 1991 and an indicator for observations after 1991; 3) **size restriction**: percentage of value-added of an industry subject to reservations for small firms and; 4) **de-licensed 1991 x post 1991 x size restriction**: product of size restriction, indicator variable for observations after 1991, and a dummy variable for industries de-licensed after 1991. All regressions include indicator variables for year (1987 through 1994) and are weighted by the value-added share of the sector. Regressions (1) and (3) also include a dummy for industries de-licensed in 1985. Standard errors are clustered by sector. Number of observations = 2,644.
